On the first day, the children read a text in intermittent broadband noise at 80 dBA L_{eq} , and the number of lines read within the 12-min time limit was noted. On the second day, the children were tested for long-term memory (recall) in silence. We introduced noise exposure during encoding to make the task more difficult. Children's performance on this test is sensitive to acute noise exposure (Hygge, 1997). For the short-term memory test, strings of consonants were presented one per second over headphones. Randomly, the sequence was stopped, and the children were asked to write down as many consonants as they could remember, in the correct position, starting at the end of the sequence. Letters in the correct or adjacent positions were scored as correct. Acute noise is known to impair performance on this task (Hamilton et al., 1977).

Attention

Two indices of general attention were used: visual search and reaction time. The visual search task is sensitive to ventilation noise (Hygge, 1991) and chronic stress (Baum, Gatchel, & Schaeffer, 1983). For this task, the children were presented with 12 complex figures and 5 simple target figures and asked to identify which one of the target figures was embedded in each complex figure. In the reaction time task, the children responded to random occurrences of red and green lights by pressing two different buttons. The children performed this task first in a silent 5-min session and then in an equally long session with aircraft noise at 85 dBA L_{eq} .

Speech perception

The speech perception measure was adapted from Hygge, Rönnerberg, Larsby, and Arlinger (1992). The children heard a story against different noise backgrounds (aircraft noise, road noise, and broadband noise) and used buttons labeled "+" and "-" to adjust the sound level of the story when it dropped randomly by 10 dBA. They were instructed to readjust the volume to the point where they could understand what was said if they concentrated. Noise-exposed children appear to ignore or tune out speech-relevant stimuli (Cohen et al., 1973, 1986; Evans & Maxwell, 1997) and are expected to require better signal-to-noise ratios than children who have not been exposed to noise.

RESULTS

Noise Levels

Noise levels were measured with a Brüel & Kjær (Copenhagen, Denmark) Community noise-level analyzer for a 24-hr period during data collection at the mobile laboratory. The expected changes in noise levels were observed at both airports (see Table 1).

Table 1. Noise levels (24-hr dBA L_{eq}) before and after the airport switch

Airport and group	Before switch (Wave 1)	After switch (Wave 3)
Old airport—aircraft noise	68	54*
Old airport—no aircraft noise	59	55
New airport—aircraft noise	53	62
New airport—no aircraft noise	53	55

*This number is an average from Waves 2 and 3 because there was only one observation in Wave 3, at a suspect value of 49.

Reading

On the word-list part of the reading test, only difficult words showed differences between the groups (see Fig. 1). The Airport \times Group \times Wave interaction was significant, $F(2, 252) = 5.10, p = .007$. (All F tests with repeated measures of wave were treated as multivariate analyses of variance, MANOVAs, rather than univariate analyses of variance, ANOVAs. These MANOVAs yield higher p values,

Fig. 1. Mean number of errors on the difficult word list as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

and thus are more conservative, than the corresponding univariate epsilon-corrected Greenhouse-Geisser ANOVAs.) Separate *t* tests (two-tailed throughout, except as noted) showed a difference between groups at the old airport at Wave 1, $t(99) = 2.68, p = .009$, but not at Waves 2 and 3 ($ts < 1$). At the new airport, there was a marginal difference between groups at Wave 3, $t(154) = 1.80, p = .074$, but not at Waves 1 and 2 ($ts < 1$).

The results for the prose component of the reading test were similar to those for the word-list test, but not as marked. For the most difficult paragraphs (Numbers 8–12), there was a weak Airport \times Group \times Wave interaction, $F(2, 172) = 2.16, p = .118$ (see Fig. 2). Separate *t* tests revealed a difference between groups at the old airport at Wave 1, $t(82) = 2.79, p = .007$, but not at Waves 2 and 3 ($ts < 1$). At the new airport there were no significant effects.

Memory

On the long-term recall task (see Fig. 3), there was a significant Airport \times Group \times Wave interaction, $F(2, 311) = 4.25, p = .015$. Separate *t* tests showed a marginally significant difference between groups at the old airport at Wave 1, $t(104) = 1.88, p = .062$, one-tailed, but not at Waves 2 and 3 ($ts < 1.28$). At the new airport, there was a difference between groups at Wave 3, $t(208) = 2.72, p = .007$, but not at Waves 1

Fig. 2. Mean number of errors on the difficult paragraphs in the reading test as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

Fig. 3. Mean score on the long-term memory task as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

and 2 ($ts < 1.12$). For the number of lines completed, there were no noise effects.

At the old airport, the short-term memory test showed a significant Group \times Wave interaction, $F(2, 203) = 5.97, p = .004$. The poorer short-term memory performance of the noise group recovered to reach the level of the control group's performance at Waves 2 and 3 (see Fig. 4). Separate *t* tests showed tendencies toward more correct responses in the no-noise group than in the noise group at Wave 1, $t(104) = 1.70, p = .092$; the difference was in the opposite direction at Wave 2, $t(104) = 1.63, p = .108$, and there was no difference between groups at Wave 3. At the new airport, there were no differences between the groups across the waves.

Attention

For the embedded-figures task, there were no reliable interactions involving chronic aircraft noise over time.

For the reaction time task, a MANOVA of reaction time and errors together yielded an Airport \times Group \times Wave interaction, $F(4, 179) = 5.58, p = .004$. Performing the task in acute noise or no noise did not qualify this interaction, and there was no main effect of acute noise, $F_s < 1$. Only reaction time, not errors, contributed to the interaction. The aircraft-noise group at the old airport was slower than its control group

Aircraft Noise and Children

Fig. 4. Mean proportion of correct items on the short-term memory task as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

at Wave 2, $t(61) = 2.29, p = .026$, but not at the other waves ($ts < 1.34$). At the new airport, the aircraft-noise group was slower than the no-aircraft-noise group at Wave 3, $t(121) = 2.09, p = .039$.

Speech Perception

Because of apparatus failure and resulting low ns , data from Wave 2 on the speech perception task were discarded. As Figure 5 shows, speech perception improved from Wave 1 to Wave 3 at the old airport, but there was no differential improvement between the groups. At the new airport, the onset of aircraft noise seemed to block improvement in auditory discrimination from Wave 1 to Wave 3, as evidenced by the Group \times Wave interaction, $F(3, 150) = 7.63, p = .000$.

Mediation

To probe for mediation, we entered into path analyses (LISREL; Jöreskog & Sörbom, 1996) the difference scores between performance in the last and first measurement waves for the paragraph reading task, the difficult word list, the long-term memory task, the number of lines completed, the short-term memory task, and the speech perception task. The results of these path analyses were straightforward and showed a

Fig. 5. Mean dB ratio of speech to noise on the speech perception task as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

very good fit between data from both airports and one of the models (see Fig. 6). Good fits were indicated by both a high p value ($> .05$) for chi-square and a low value of the root mean square error of approximation ($< .08$; Jöreskog & Sörbom, 1996). In this model, the noise effect on the reading tasks was not mediated by memory or speech perception. For long-term memory, there was a partial mediation by the word-list component of the reading task. For all the other tested variables in different combinations there were no indications of mediating links. The value of N in this analysis was low, mainly because of participants not finishing the difficult reading paragraphs in Wave 1. However, path analyses not including reading, and thus having a higher N , yielded path coefficients between the other variables that were of approximately the same strength as shown in Figure 6.

DISCUSSION

These longitudinal data complement nearly 20 cross-sectional studies showing adverse impacts of aircraft noise on reading in elementary-school children. Moreover, these effects occur prospectively and may be reversible. We have also demonstrated prospective impacts of chronic noise on long-term memory. More work is needed to determine the sensitivity of this effect to the duration of exposure, as well as children's age.

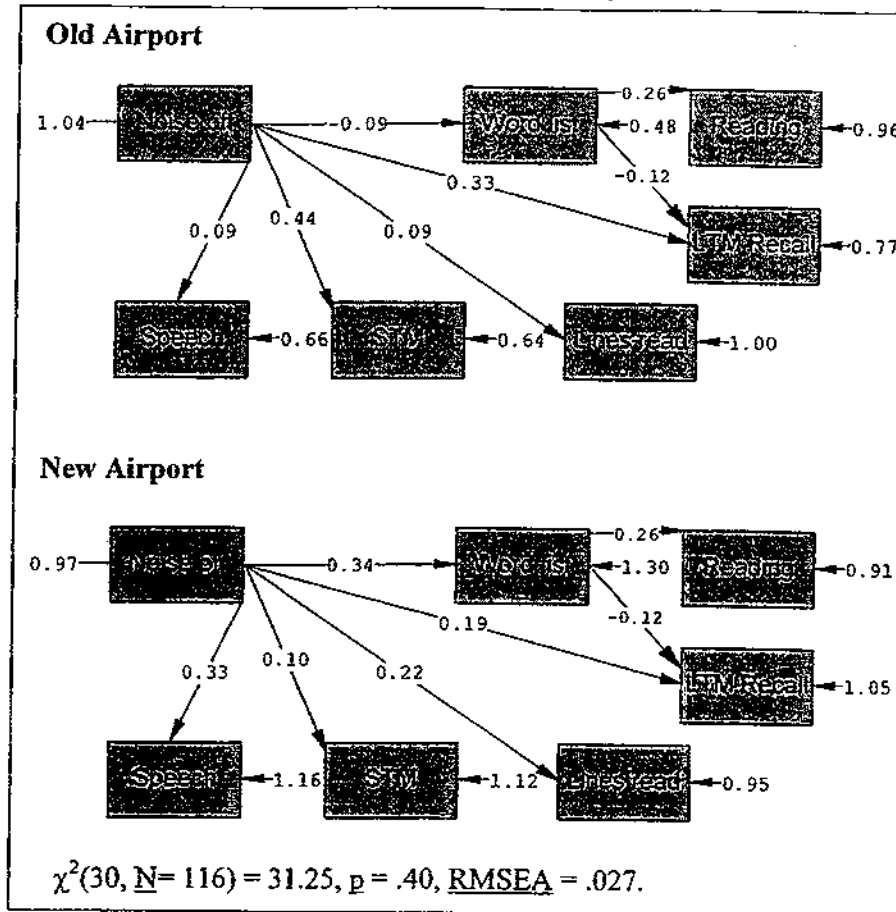

Fig. 6. Model fit (chi-square and root mean square error of approximation, RMSEA) and standardized path coefficients between cognitive measures. The cognitive measures were calculated as difference scores between the last and first measurement waves for the difficult word list ("Word list"), the paragraph reading task ("Reading"), the long-term memory task ("LTM Recall"), the number of lines completed ("Lines read"), the short-term memory task ("STM"), and the speech perception task ("Speech"). The paths from Word list to Reading (0.26) and LTM Recall (-0.12), with values in smaller print, were constrained to be equal at the two airports.

This is also the first study to show prospective impacts of chronic noise on a cognitive process, long-term memory. Weaker evidence suggests noise-induced deficiencies in speech perception and short-term memory.

Reading and long-term memory effects replicated, disappearing when the old airport closed and emerging after the new airport opened. This provides strong causal evidence for the vulnerability of central language processing to noise exposure, and the reversible nature of the impact. Additional research is needed to see whether the adverse noise effects on reading and recall continue over time. Note that at the new airport the negative effects were stronger at Wave 3 than at Wave 2, which suggests a cumulative noise effect.

The speech perception findings warrant further research. Differences in speech perception did not mediate noise effects on reading. The lack of mediation is inconsistent with prior cross-sectional studies (Cohen et al., 1973, 1986; Evans & Maxwell, 1997). The present longitudinal data raise doubts about the validity of inattention, or "tuning out," as an explanatory mechanism for the adverse impacts of noise on reading performance.

Furthermore, although children's reading worsened with cumulative noise exposure at the new airport and recovered following noise cessation at the old airport, speech perception deficits among noise-exposed children at the old airport did not recover. This suggests that speech perception did not mediate the noise effects on reading, a conclusion that is also indicated by the structural equation results. An explanation for this pattern of results may be the developmental timing of the noise exposure. Perhaps noise exposure damages the development of speech perception in different ways during the early and late portions of the reading-acquisition period.

Future research needs to address the importance of both the developmental timing and the duration of noise exposure in determining the effect of noise on reading and cognitive development. Research also needs to sample a wider range of noise levels in order to generate a dose-response function for reading, which would provide additional basic evidence and better inform public policy for noise protection of children.

Acknowledgments—This study was conducted while Staffan Hygge was with the National Swedish Institute for Building Research and with Kungl Tekniska Högskolan—Royal Institute of Technology, both in Gävle, Sweden. We are grateful to the families who cooperated with this research. We thank Gerhard Helm, Sylvia von Mackensen, Markus Meis, Gunnar Söderqvist, and Christian Wigren for their dedication to the project. This research was partially supported by the Society for the Psychological Study of Social Issues, the National Institute of Health (R01 HL 4732 01A), the National Institute of Child Health and Human Development (1 F33 HD 08473-01), the Nordic Scientific Group for Noise Effects, the Swedish Environmental Protection Agency, the German Research Foundation (DFG), and the National Swedish Institute for Building Research. The third author was also supported by a DFG Heisenberg Fellowship. We are particularly grateful to Nils Antoni, former director of the National Swedish Institute for Building Research, who efficiently made necessary funds available at the outset of the Munich study.

Nonauditory Effects of Noise on Children: A Critical Review

Gary W. Evans
Cornell University
New York, USA

Stephen J. Lepore
Carnegie Mellon University
USA

Large numbers of children both in the United States and throughout the economically developing world are chronically exposed to high levels of ambient noise. Although a great deal is known about chronic noise exposures and hearing damage, much less is known about the nonauditory effects of chronic ambient noise exposure on children. To estimate the risk of ambient noise exposure to healthy human development, more information about and attention to nonauditory effects such as psychophysiological functioning, motivation, and cognitive processes is needed. This article critically reviews existing research on the nonauditory effects of noise on children; develops several preliminary models of how noise may adversely affect children; and advocates an ecological perspective for a future research agenda.

Keywords: noise, stress, nonauditory effects, health, cognitive

INTRODUCTION

In 1973 nearly 10 million American school children were exposed to ambient noise levels that exceed federal standards for hearing protection in work settings (Environmental Protection Agency, 1974). Recent studies estimate that American children on average are exposed daily to noise levels in the range of 76-80 Leq (unweighted average of decibel levels for 24 hours) (Roche et al., 1982; Schori & McGatha, 1978). To put these figures in perspective, the EPA recommended limit for risk to hearing is 70 Leq daily exposure for children. Since these assessments of childhood noise exposure, there have been marked increases worldwide in the number of children exposed to noise levels loud enough to impair hearing: this is especially true in underdeveloped countries (Evans, 1990; Suter, 1991).

Many *nonauditory* effects of noise on children also have been detected during the past two decades of research. Nonauditory effects of noise refer to impacts not directly related to sound-

induced damage to the auditory system. Non-auditory effects of noise, such as elevated sympathetic nervous system activity or disturbances in attentional processes, are apparent in children exposed to noise levels far below those necessary to induce auditory damage.

Although there is abundant evidence and analysis of the auditory effects of noise on children (Kryter, 1985; Mills, 1975), there has been little systematic, critical analysis of the nonauditory effects of noise exposure among children. This is a critical omission if we are interested in estimating the true risk of noise exposure to healthy human development. The present article critically examines the empirical evidence on the nonauditory effects of noise on children. The work is organized into three general areas of functioning: physiological, motivation, and cognitive. Both conceptual as well as methodological limitations in the extant research are examined.

Physiological Effects of Noise

Work in animal models and in various occupational settings suggests heightened activation of the cardiovascular system among organisms

Table 1. Effects of noise on cardiovascular outcomes

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Brackbill et al. (1982)	HR	1 h white noise for 4 consecutive days. 50 and 75 dBA.	(78 males) ages 1 mon. to 80 yrs.	In infants and 8-year olds, HR decreased as sound levels increased. No other main or interactive effects of noise.
Cohen et al. (1980)	BP	Aircraft. 95 dBA peak.	(262) grades 3-4.	Noisy-school children had higher SBP and DBP than quiet-school children.
Cohen et al. (1981)	BP	Aircraft. 95 dBA peak.	(163) grades 3-4, longitudinal sample.	In the longitudinal attrition sample, there were no effects of noise on BP.
Cohen et al. (1986)	BP	Aircraft. 16 dBA sound reduction in noise-abated classrooms.	(163) grades 3-4, longitudinal sample.	SBP marginally lower and DBP significantly lower in quiet- than noisy-school children. SBP and DBP marginally lower in quiet- than noise-abated school children. No BP differences in children in noisy vs. noise-abated school.
Cohen et al. (1986)	BP	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Noisy-school children had higher BP than quiet-school children if were enrolled for 2 yrs or less. No noise effects on children enrolled more than 2 yrs.
Karsdorf & Klappach (1968)	BP	Traffic and street. 63-84 phon.	(262) grades 7-10.	Children in quiet schools had normal BP; whereas those in moderately- to very-noisy schools had elevated BP, especially among older boys.
Ising et al. (1990)	BP	Low altitude military flights. 125 dBA peak/Leq 68 dBA.	(433) ages 10-13 yrs.	Noise-related increases in SBP and DBP for girls, but not boys. Noise-related HR deceleration in boys and girls, but deceleration only significant in boys.
Karagodina (1969)	BP	Aircraft. 112 dBA peak/Leq 58 dBA.	(unavailable) ages 9-13 yrs.	Noisy-school children had higher BP than quiet-school children.
Roche et al. (1982)	BP	Self-report of exposure to loud noise sources. 80-Leq.	(233) ages 12-14 yrs.	Self-reported noise exposure levels not associated with BP.

Note: HR = heart rate, BP = blood pressure, S = systolic, D = diastolic.

chronically exposed to noise (Kryter, 1985; Smith, in press). As shown in Table 1, several studies have also uncovered evidence of possible linkages between chronic noise exposure and elevated blood pressure among children.

With two exceptions, all of the studies shown in Table 1 report elevations of resting blood pressure among children chronically exposed to noise. The one experimental study (Brackbill et al., 1982) found habituation to noise, which is a well established psychophysiological finding with short-term noise exposures (Glass & Singer, 1972). The extent of blood pressure elevations found from chronic exposure are probably not clinically significant for children during their youth (Voors et al., 1976), but could portend elevations later in life that might be health damaging (Berenson, 1980). To our knowledge,

there have been no long-term follow up studies of children exposed to noise at an early developmental stage. We know essentially nothing about the long-term consequences of early noise exposure on developing cardiovascular systems.

Both of the studies in Table 1 that found nonsignificant correlations between noise exposure and chronic blood pressure levels have methodological limitations. Roche et al. (1982) relied on children's retrospective reports of exposure to noise events (e.g., motorcycle use) during the previous six months. No data were presented on the reliability or validity of these noise estimates. Furthermore, the children monitored did not live near especially high noise sources (e.g., airports). Instead exposure to point noise sources such as machinery was estimated. Finally, resting blood pressure was only estimated

with one reading. On the other hand, this is the only study to examine the association between typical, daily noise exposures and resting blood pressure among children. All other studies have assessed the association between chronic blood pressure and exposure to high noise sources such as airports, roads, or trains. Analyses of the health effects of typical noise exposure for children are needed but with more adequate measurements of both noise exposure and blood pressure.

The second study to find a nonsignificant association between chronic noise exposure and resting blood pressure levels was conducted with children exposed to high levels of noise from an airport. Cohen et al. (1981) found that a difference in blood pressure between children attending noisy versus quiet elementary schools in a cross-sectional analysis did not replicate when reassessed one year later. Attritional analyses suggested that the failed longitudinal replication was caused by emigration of the families of children in noisy areas with the highest levels of blood pressure. Among children attending quiet schools, on the other hand, there was no selective attrition related to blood pressure levels.

Unlike other studies listed in Table 1, the three studies by Cohen and colleagues (Cohen et al., 1980; 1981; 1986) include statistical controls (e.g., social class, education) to counter potential third variable explanations of the associations uncovered between noise exposure and chronic levels of blood pressure. However, none of the studies is prospective, nor do any show a dose response relation between noise and blood pressure. Furthermore, all of the extant studies have relied upon gross indices of noise exposure - typically peak readings measured at schools.

Noise in the fetal and neonatal environment may be particularly harmful to fetuses and newborns because they are in a period of great organismic plasticity. It is well established that environmental sounds and vibration influence physiological and behavioral responses in the fetus (Pikus, 1991). There are contradictory data on the relations between ambient noise exposure and birth weight (for reviews see Pikus, 1991; Smith, in press) but little or no definitive evidence for teratological effects of chronic noise exposure (Edmonds et al., 1979; Meyer et al., 1989). Nonetheless, it is critical for more thorough and extended investigation of the potential impacts of routine modern medical procedures such as ultrasound monitoring or

placement of premature babies in intensive care nurseries with extremely noisy equipment (Gottfried et al., 1981; Lawson et al., 1977).

Summary

Residing or attending school near a major noise source is associated with elevated blood pressure. More research is clearly called for, especially tracking children before, during, and after exposure to noisy environments. All evidence to date is correlational and even though some studies have included good controls, stronger, quasi-experimental designs are needed to firmly tie noise to the etiology of cardiovascular changes in children. The degree of blood pressure elevations is small, on the order of 4-8 mm of mercury, but these elevations do not appear to habituate with continued exposure (cf., Cohen et al., 1986). The clinical significance of such changes in childhood blood pressure is difficult to determine. The ranges of blood pressure among noise-exposed children are within normal levels and do not suggest hypertension. On the other hand, elevations in blood pressure among children appear to track into adulthood (Beren-son, 1980), increasing the potential risk for cardiovascular disease. It would also be of value to examine neuroendocrine makers of stress (e.g., cortisol) that have been implicated in the casual pathways between stressors and cardiovascular outcomes.

Emotional/Motivational Effects of Noise

The uncontrollability of chronic noise exposure may affect childrens' emotional and motivational states. When organisms are exposed to repeated, uncontrollable events, learned helplessness can occur (Abramson et al., 1978; Seligman, 1975). Learned helplessness means the organism learns that the outcomes of its behavior are independent of its responses. Learned helplessness is manifested as a lack of effort or responsiveness to environmental stimuli and challenges. Uncontrollable noise has been shown to induce helplessness in adults (Hiroto, 1974; Hiroto & Seligman, 1975; Krantz et al., 1974). Moreover, adults immediately following exposure to uncontrollable noise are less likely to persist on difficult or challenging aftereffect puzzles than their counterparts with prior exposure to controllable noise (Cohen, 1980; Glass & Singer, 1972).

Overall, though, very little is known about the

Table 2. Effects of noise on motivation (learned helplessness)

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Cohen et al. (1980)	Performance on moderately difficult puzzle after pretreatment with insoluble or soluble puzzle.	Aircraft. 95 dBA peak.	(262) grades 3-4.	Noisy-school children failed more on pretreatment soluble puzzle and difficult test puzzle, and were more likely to give up on difficult puzzle, than quiet-school children. There was a nonsignificant trend suggesting that longer exposure to a noisy school was associated with greater time to complete difficult puzzle.
Cohen et al. (1981)	Performance on moderately difficult puzzle.	Aircraft. 95 dBA peak.	(163) grades 3-4, longitudinal sample.	Noisy-school children were more likely to fail at the test puzzle and to take longer to solve the puzzle than quiet-school children. No noise effect on rate of giving up.
Cohen et al. (1981)	Performance on moderately difficult puzzle.	Aircraft. 16 dBA sound reduction in noise-abated classrooms.	(163) grades 3-4, longitudinal sample.	Sound attenuation improved children's performance on the original test puzzle.
Cohen et al. (1986)	Performance on moderately difficult puzzle.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Noisy-school children failed difficult puzzle more frequently than did quiet-school children.
Cohen et al. (1986)	Choice task.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Noisy-school children more likely than quiet-school children to give choice of reward to experimenter.
Moch-Sibony (1984)	Rosenzweig frustration tolerance test.	Aircraft. 29 vs 54 SIL.	(80) kindergarten.	Noise-related decreases in frustration tolerance.
Wachs (1987)	Observer ratings of mastery-oriented play behavior.	Ratings of noise: 1 = normal level voices in home for 15 min. period to 4 = noisy level voices in home for more than half 15 min. period.	(88) 12 mon.	Less mastery-oriented play behavior in noisier homes.

Note: SIL = speech interference level.

relations between chronic exposure to environmental stressors such as noise and the induction of helplessness in human beings. Community surveys of noise annoyance frequently note that while annoyance is common, complaints or other actions to intervene are rare (Evans & Tafalla, 1987). Most residents who are annoyed by noise report feeling unable or helpless to alter the situation (Jue et al., 1984). The small minority who do complain or take other actions report feeling greater self-efficacy to cope with the noise (Jue et al., 1984).

As shown in Table 2, a few studies have examined the effects of noise on children's motivational states. The significant relations between noise exposure and motivational deficits in one cross-sectional study (Cohen et al., 1980) were replicated both in a longitudinal study (Cohen et al., 1981) and in a second, cross-sectional study

(Cohen et al., 1986). Higher noise exposure in children has been associated with reduced persistence on challenging puzzles and greater abdication of choice over rewards (see Table 2). Perhaps the most persuasive data of reduced motivation in an achievement related situation is Cohen et al.'s (1980) findings on giving up. Not only were children from noisy schools less likely to solve a challenging puzzle within a four minute time period, a substantially greater proportion of them (15%) simply gave up before the allotted time had elapsed, often remarking that they couldn't do the task, in comparison to 2% of their quiet school counterparts who gave up.

Of additional interest, teachers from schools located in noisy settings report more difficulties motivating students to perform than do teachers from relatively quiet schools (Crook & Langdon, 1974; Kyzar, 1977; Moch-Sibony, 1984).

Even very young children appear to be less motivated to engage in object mastery or control over their environment, after prolonged exposure to noise. For example, 12-month-old infants living in noisier households tended to engage in less effective, mastery-oriented interactions with toys in their homes than did children from relatively quiet homes (Wachs, 1987).

Learned helplessness is more apt to occur when individuals make stable, personological attributions (e.g., ability) rather than ascribe global or temporary reasons (e.g., bad luck, poor effort) for their failures (Abramson et al., 1974; Silver et al., 1982). No research on noise and motivation has examined these underlying attributional processes. Future research should also directly manipulate contingencies in a task (e.g., provision of insoluble puzzles) and then examine differences in tendencies to become helpless along with attributional measures, as a function of chronic noise exposure. In addition, researchers should examine the possible mental health consequences of noise-related learned helplessness. If noise heightens vulnerability to helplessness, then it is reasonable to suspect possible connections between chronic noise exposure and certain psychological problems in children. In one exploratory study, Wachs (1988) found a positive association between noise levels in the home and adaptability, but noise was unrelated to several other indices of temperament. In another study, a composite index of noise and confusion/clutter in the home was linked to difficulty in care requirements for 18-month-old children, although not for 12-month or 24-month-olds (Wachs, 1989)

Summary

Brief exposures to uncontrollable noise are capable of inducing learned helplessness in adults. Chronic residential exposure to noise also appears to be associated with feelings of helplessness among adults living nearby airports. Although the evidence is scant, there are suggestive findings indicating that children chronically exposed to ambient noise sources may be more vulnerable to learned helplessness. Children attending schools in airport flight paths are less likely to solve or persist in attempting to solve challenging puzzles. They are also more likely to abdicate choice over a reward to an adult rather than exercising the choice option themselves. Teachers of children in noisy schools also report, on average, greater difficulties in

motivating children in their school work. Noise in the home may be associated with mastery motivation in very young children. In addition to the small number of studies, all of which are correlational, another drawback to this area of work has been a lack of systematic integration of more sophisticated developmental paradigms for the measurement of motivational deficits in children. The potential pathways among chronic noise exposure, helplessness, and psychological health warrant further research.

Cognitive Effects of Noise

Research on the cognitive effects of noise exposure on children has received the most attention from researchers. This area of research can be subdivided into three subtopics: (i) attention and perception, (ii) memory, and (iii) intellectual achievement.

Attention and perception

The cognitive ability to perceive order and contingency in the environment presumably depends on some modicum of sustained attention to event sequences as they unfold. The interruptive, distracting effects of high ambient noise levels might directly affect the young child's ability to sustain voluntary attention or to concentrate (Heft, 1985).

As shown in Table 3, studies by Karsdorf and Klappach (1968), Kyzar (1977) and by Moch-Sibony (1984) have revealed deficits in standardized measures of sustained attention among children chronically exposed to noise. The standardized tests involve searching for target geometric stimuli from among fields of similar objects. In addition, teachers report that children in noisy schools tend to have more difficulties in concentrating in comparison to children from relatively quieter schools (Crook & Langdon, 1974; Ko, 1979; Kryter, 1985; Kyzar, 1977).

Cognitive studies on children with variable exposures to chronic noise sources also indicate possible decrements in visual attention (see Table 3). Children from noisy homes took longer to locate target pictorial stimuli within an array of pictures than did children from relatively quiet homes (Heft, 1979). Children attending daycare centers located near train tracks performed marginally more poorly on a visual search task

Table 3. Effects of noise on attention

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Crook & Langdon (1971)	Teachers' reports of concentration.	Aircraft. 75 dBA peak.	(76 teachers) primary and secondary.	Teachers in noisy schools reported more concentration problems in students than did those in quieter schools.
Hambrick-Dixon (1986)	Cross-out letters in quiet or noise.	Train. 108 dBA peak.	(109 black) ages 4-6 yrs.	Children from noisy daycare performed task marginally worse than children from quiet daycare.
Hambrick-Dixon (1988)	Visual stimulus detection with verbal or key press response.	Train. 108 dBA peak.	(102 black) ages 5-7 yrs.	interaction between location of daycare, response mode, exposure duration, and sex: On key response, girls in noisy daycare less than 2 yrs made more errors than girls in quieter daycare less than 2 yrs. On verbal response, girls in noisy daycare more than 2 yrs made more errors than girls in quiet daycare more than 2 yrs. No differences in performance of boys in any condition.
Heft (1979)	Response latency in visual search.	Noise ratings: 1 = low to 7 = high.	(94) ages 4-7 yrs.	Higher household-noise level associated with longer response latency.
Karsdorf & Klappach (1968)	Errors and latency on Bourbon test.	Traffic and street. 63-84 phon.	(262) grades 7-10.	Noisy-school students had longer response latency and more errors than quiet-school students.
Ko (1979)	Teachers' reports of concentration.	Aircraft. 105 dBA peak.	(2100 teachers) primary and secondary.	Teachers in noisy schools reported more concentration problems in students than did those in quieter schools.
Kyzar (1977)	Minnesota clerical test.	Traffic and street. 62-94 dBA.	(56) elementary school.	Noise-related deficits in clerical-type task.
Kryter (1985)	Teachers' reports of concentration.	Aircraft. 87 dBA peak.	unavailable.	Teachers in noisy schools reported more concentration problems in students than did those in quieter schools.
Moch-Sibony (1984)	Zazzo sustained attention task.	Aircraft. 29-54 SIL.	(80) kindergarten.	Noisy-school children had poorer sustained attention than did quiet-school children.
Acute noise				
Zentall & Shaw (1980)	Visual search for letters.	Taped class noise from free time (71 dBA) and work time (57 dBA).	(36) grade 2 (hyperactive and non-hyperactive controls).	Noise x Hyperactivity interaction; Hyperactive children made fewer commission errors in low than in high noise conditions; non-hyperactive children unaffected by noise.

Note: SIL = speech interference level.

than did children from relatively quiet daycare centers (Hambrick-Dixon, 1986). In a subsequent study, Hambrick-Dixon (1988) uncovered a more complex relation between chronic noise exposure and attention, utilizing a vigilance task: Gender, exposure duration to train noise at the daycare center, and the response mode for the task (naming versus pressing a key) moderated the association between noise and performance.

Unfortunately, several of the sustained attention and noise studies suffer from methodological shortcomings. The Kyzar (1977) and Karsdorf and Klappach (1968) studies have inadequate controls

for sociodemographic factors. Furthermore, all of the studies are cross-sectional and only the Moch-Sibony (1984) study carefully screened children for normal hearing. The Heft (1979) study relied upon observer ratings of home noise levels, no actual noise measurements were taken.

The Hambrick-Dixon (1988) results are particularly complex and difficult to interpret. One possible explanation for the inconsistency between her results and those of other researchers is that she measured the ability of children to detect a visual signal using tachistoscopic presentation times (100 msec). Thus rather than

Table 4. Effects of noise on auditory discrimination/speech perception

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Cohen et al. (1973)	WAD	Traffic and street. 55-66 dBA.	(54) grades 2-5.	Noise associated with poorer auditory discrimination.
Cohen et al. (1980)	WAD	Aircraft. 95 dBA peak.	(262) grades 3-4.	No effects of noise on auditory discrimination.
Cohen et al. (1986)	WAD	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	No effects of noise on auditory discrimination.
Moch-Sibony (1984)	MP	Aircraft. 29 vs 54 SIL.	(80) kindergarten.	Noise associated with poorer auditory discrimination.
Acute noise				
Blue & Vergason (1975)	GFW	Recorded sounds (unspecified). 55 dBA.	(34) grades 1,3.	Race x Noise interaction: Black children's performance affected more negatively by noise than was white children's performance.
Nober & Nober (1975)	WAD	Recording of classroom noise vs ambient noise. 39.5-64.7 dBA.	(39) ages 5-7 yrs (healthy control, retarded, and speech-deficit).	Fewer errors when tested in quiet vs. normal classroom noise levels. Control and retarded children performed worse in noise than in quiet; speech-deficit group performed worse in noise than in quiet, but the effect was not significant.
McCroskey & Devens (1977)	WAD	Classroom noise recording. 4 dBA above ambient classroom noise	Unavailable.	Noise associated with decrements in auditory discrimination.
Glenn et al. (1978)	Speech discrimination	Recorded hospital sounds. 75 dB SPC (typical for hospitals).	(21) ages 9-14 yrs (institutionalized MR).	Noise mask significantly degraded speech discrimination.
Laraway (1985)	Digit discrimination	Intermittent white noise. 80 dB SPC.	(46) ages 5-21 yrs (CP, healthy controls).	Noise mask degraded performance of CP children but not controls. Noise effects greatest in younger (< 7 yrs) children.
Laskey & Tobin (1973)	Message comprehension	Speech and white noise. 74 dB SPC.	(22) ages 6-8 yrs (possible LD, non-LD controls).	Speech, but not white noise, interfered with auditory message comprehension in LD children. Control children unaffected by noise.

Note: WAD = Wepman auditory discrimination test, GFW = Goldman-Fristoe-Woodcock auditory discrimination task, MP = Massiot Phillips auditory discrimination test, SIL = speech interference level, LD = learning disabled, CP = cerebral-palsied, MR = mentally retarded.

measuring sustained visual attention, Hambrick-Dixon probably measured signal detectability.

As expected given the physical properties of noise, considerable attention has been given to auditory information processing among children exposed to chronic or acute noise sources. One of the cognitive strategies that children may learn in order to adapt to the distracting properties of chronic noise is to filter or tune out unwanted auditory stimuli. The tendency of children in noisy environments to tune out noise may become overgeneralized, such that various types of acoustic stimuli, including speech, are not attended to carefully (Deutsch, 1964). In a direct

test of the tuning out hypothesis, Cohen et al. (1973) compared the ability of children living in quiet and noisy apartments (proximity to a freeway) within the same building to discriminate between similar sounds under quiet conditions. Cohen et al. (1973) as well as Moch-Sibony (1984) found an association between chronic noise exposure and auditory discrimination (see Table 4). Both of these studies had good controls for socioeconomic status, and pre-screened children for hearing loss. Moreover, Cohen et al. (1973) showed that with longer exposure durations, the association between noise and deficits in auditory discrimination became stronger.

Table 5. Effects of noise on resistance to auditory distractors

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Cohen et al. (1980)	Cross-out letters in ambient or distracting (story recording) condition.	Aircraft. 95 dBA peak.	(262) grades 3-4.	Noise × Month enrolled interaction: with less than 2 yrs enrollment, noisy-school children performed better than quiet-school children under distraction. Between 2-4 yrs enrollment, no noise effects. With more than 4 yrs enrollment, noisy-school children performed worse than quiet-school children.
Cohen et al. (1981)	Cross-out letters in ambient or distracting condition.	Aircraft. 95 dBA peak.	(163) grades 3-4, longitudinal sample.	With 2-4 years enrollment, noisy-school children were less distracted than quiet-school children. With more than 4 yrs enrollment, performance was nearly the same across conditions.
Cohen et al. (1986)	Cross-out letters in ambient or distracting condition.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Children attending noisy schools for 2-4 yrs were less distracted than their quiet-school counterparts. However, after 4 yrs enrollment, performance was nearly the same across conditions.
Cohen et al. (1981)	Cross-out letters in ambient or distracting condition.	Aircraft. 16 dBA reduction in noise-abated classrooms.	(163) grades 3-4, longitudinal sample.	No effects of noise abatement on distractibility.
Hambrick-Dixon (1986)	Weschler IQ task and match animals with color disks in quiet or noise conditions.	Train. 108 dBA peak.	(109) black) ages 4-6 yrs.	Children from noisy daycare performed better in noisy than in quiet conditions. The opposite was found for children from quiet daycare centers.
Heft (1979)	Figure discrimination in matching task in quiet or noise.	Story reading. Noise ratings: 1 = low to 7 = high.	(94) ages 4-7 yrs.	Auditory distraction had less of a negative effect on children from noisy homes than on children from quiet homes.
Acute noise				
Turnure (1970)	Performance and glances away from a visual discrimination task.	Recording of child songs/stories. 60 dBA.	(30) ages 5.5, 6.5, 7.5 yrs.	No noise effects on glances, but performance worse in noisy than in quiet conditions.
Steinkamp (1980)	Multiple perceptual and cognitive tasks.	Classroom sounds and gadgets. Ambient noise.	(24) ages 6-8 yrs (hyperactive, non-hyperactive controls).	Classroom noise and distracting visual materials caused deficits on most tasks. No interaction with hyperactivity.

In two subsequent studies, Cohen et al. (1980; 1986) were unable to replicate these findings on noise and auditory discrimination using a different noise source (aircraft as opposed to traffic). The traffic noise study (Cohen et al., 1973) also drew primarily from working class families; whereas the airport study was conducted in a poverty area. Using a different auditory discrimination task, however, did reveal deficiencies in auditory discrimination in children chronically exposed to noise from airports (Cohen et al., 1986). Children were presented a constant signal (man reading a story) superimposed against four different white noise backgrounds. The task was

to choose the optimum signal to noise ratio. Children who attended noisy schools for longer periods were significantly poorer at this signal to noise discrimination task (see Table 4).

Not surprisingly, the acute noise experimental studies in Table 4 indicate that children have difficulty with auditory discrimination during acute noise exposure (Blue & Vergason, 1975; Glenn et al., 1978; Laraway, 1985; Nober & Nober, 1973). Thus noise can directly interfere with children's ability to discriminate between meaningful auditory stimuli. Noise, particularly irrelevant speech, also interferes with comprehen-

sion of spoken language (Glenn et al., 1978; Laraway, 1985; Lasky & Tobin, 1973). The Glenn et al. (1978) data are noteworthy because the researchers used simulated recordings of an institutional setting for the mentally retarded as their noise 'mask'. Typical, ambient levels from the institution were sufficient to produce marked deficits in discriminating speech sounds among mentally retarded children.

Although there are clear overall trends showing that concurrent noise can mask auditory discrimination, as well as speech, there may be individual differences in these effects. Blue and Vergason (1975) found racial differences in auditory discrimination with black children being more adversely affected than white children by concurrent noise. This study was conducted in the Southeastern United States and may not have controlled for the dialect used in stimulus materials. Laraway (1985) reported that only cerebral palsied children were adversely affected by a noise mask in a task in which children were asked to repeat auditorily presented digits. Lasky and Tobin (1973) revealed that only children with suspected learning disabilities had difficulties in tracking an auditory signal against a background of competing, irrelevant speech. The latter study also showed that speech, but not white noise of a similar volume, interfered with message comprehension.

An interesting and provocative question raised by Deutsch's original hypothesis and some of the subsequent empirical work is whether children chronically exposed to noise become so adept at filtering out noise, that they become resistant to its distracting properties. A number of studies shown in Table 5 present suggestive evidence in support of this hypothesis of differential resistance to noise distractors. However, the data are complex.

Kindergarten children from noisy homes were less distracted by irrelevant speech during a visual discrimination task than those from quiet homes (Heft, 1979). In this task, children selected one of several figures that correctly matched a standard figure. Cohen and colleagues (1980) found a similar pattern of results, but only for elementary students exposed to aircraft noise for two years or less. For those exposed longer, auditory distraction during a visual search task (crossing out e's in a text above reading level of the child) interfered more with the performance of noisy-

school children than it did for quiet-school children. This effect was also replicated in a different sample (Cohen et al., 1986). Hambrick-Dixon (1986) uncovered an even more complex pattern of data on a visual coding task among very young children. In this task preschool children placed colored discs next to animal drawings according to an initial set of model comparisons. For children from noisy daycare centers, performance on this task was better under noisy testing conditions than quiet ones; whereas for children from quiet daycare centers, performance was superior during quiet testing conditions than under noisy ones.

Thus, although there is some evidence that children chronically exposed to noise are less distractable by auditory stimuli during a task, with very long exposure (4+ years), they appear to lose this advantage over non-noise-exposed children. Children exposed for short periods of time to chronic noise, may be able to gate out auditory distractors more effectively during tasks; whereas children exposed for long periods of time, may lose this gating ability. This could occur because despite sustained efforts to gate out unwanted sounds, children learn that this coping strategy is ultimately ineffective since the noise remains as a potent distractor.

The type of task, type of noise, and some individual difference variables also may influence whether concurrent auditory stimuli are distracting during task performance. For example, although both Heft (1979) and Cohen et al. (1980; 1986) found that concurrent speech distracted children during a visual search task (finding target objects in a matrix, crossing out target letters in text, respectively), Hambrick-Dixon (1986) had no main effect of a distractor (background noise of a daycare free play period) on performance of a visual matching task (placement of colored discs next to animal drawings). Turnure (1970) found a distracting effect of speech on school children's performance on a visual discrimination task (choosing the odd geometric shape out of three stimuli). However behavioral manifestation of distraction (glancing up) was not observed. Zentall and Shaw (1980) found that classroom noise recordings did not affect a visual letter search task for normal children and degraded performance for hyperactive, elementary-aged children. Finally, Steinkampf (1980) found that the combination of recorded classroom sounds

Table 6. Effects of noise on memory

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Hambrick-Dixon (1986)	Serial, incidental, visual, paired-associates learning.	Train. 108 dBA peak.	(109 black) ages 4-6 yrs.	No noise effects.
Heft (1979)	Incidental memory of visual stimuli.	Noise ratings: 1=low to 7=high.	(94) ages 4-7 yrs.	Higher household noise level associated with poorer incidental memory.
Acute noise				
Fenton et al. (1974)	4 number digit-span.	White noise. 22-72 dBA.	(10 male) ages 9-11 yrs (LD and non-LD).	More errors made in the high noise than in the low noise conditions.
Hygge (1993)	Recall and recognition of reading passage.	Recorded simulations of aircraft, train, traffic, and verbal noise. 66-76 dBA.	(417) ages 12-14 yrs.	Within-subjects analyses revealed a marginal Noise x Source interaction: recall on difficult questions was lower among children in aircraft and traffic noise conditions than in control conditions; no differences in recall in train and verbal noise conditions relative to control condition. Between-subjects analyses also revealed a Noise x Source interaction: recall on difficult questions was lower among children in aircraft noise conditions than in controls; other noise sources did not affect recall. No noise effects on recognition task. Individual differences in learning ability did not moderate noise effects.
Johansson (1983)	Paired-associates learning and letter memory.	White noise. 51 dBA continuous; 55-78 dBA intermittent.	(66) age 10 yrs.	No noise effects.

Note: LD = learning disabled.

played at normal volume and the presence of interesting gadgets were distracting for several tasks among normal and hyperactive boys. Because the latter study did not separate ambient noise from visual distractors, the specific effects of noise cannot be determined.

It is difficult to discern any clear patterns in the above findings on acute, concurrent noise and distraction among children. Speech, as opposed to background noise (e.g., recordings of classroom noise), may be more distracting during task performance. Unfortunately since no studies have used the same task with different aged children, we cannot infer any developmental trends from the data. However it is noteworthy that studies showing no effects tested the youngest children.

Summary

Children chronically exposed to noise may suffer from attentional deficits. Although suggestive,

the work in this area suffers from sufficient methodological flaws (e.g., controls for SES) to prohibit definitive conclusions. Children chronically exposed to noise develop cognitive strategies to cope with the interruptive, distracting influence of noise. Some data suggest that children learn to ignore or tune out auditory stimuli if they have been chronically exposed to noise. At least during the first few years of exposure, children from noisy residential areas appear to be more resistant to acute auditory distractors, presumably because of their enhanced ability to tune out auditory stimuli. These same children may suffer deficits in auditory discrimination. Acute noise distracts children during cognitive task performance, especially when the distractors contain meaningful speech. These acute auditory distraction effects may be more problematic for certain subgroups of children, especially those with some pre-existing cognitive deficits. More research, particularly on groups potentially at risk should be a high priority.

Memory

The noise and memory literature on children (Table 6) is sparse but generally in agreement with the adult literature (Cohen et al., 1986; Smith, in press). There appears to be little or no effects of noise on simple memory tasks from chronic exposure (Hambrick-Dixon, 1986) or acute exposure (Johansson, 1983). However, if sufficient processing demands are placed upon memory, deficits begin to appear in children exposed to noise (Fenton et al., 1974; Hygge, 1993).

Hygge's (1993) experimental findings (see Table 6) are interesting because he compared relatively easy and difficult memory tasks under quiet and noisy conditions, finding that only the difficult tasks were sensitive to noise exposure. Heft's (1979) incidental memory deficits are also noteworthy because they fit with a typical noise and memory finding in adults. The adult incidental memory studies have been interpreted as indicative of attention narrowing or focusing on dominant stimuli (Cohen et al., 1986). Attention narrowing appears to be common under arousing conditions in general (Broadbent, 1971) and under noise specifically (Hockey, 1979). Greater attention to more central cues could lead to poorer encoding of more peripheral material.

Summary

Although there is little research on children's memory under chronic or acute noise conditions, the data are generally in accord with the adult literature on the subject. Noise exposure has little if any effect on children's short term or working memory. Memory tasks that put especially demanding loads on working memory, however, may show some deficits. Narrowing of attention to more central cues under noise may cause poorer memory for incidental information. The potential role of attentional processes in noise-related memory effects warrants further scrutiny.

Intellectual Achievement

Given the reasonable possibility that chronic noise exposure interferes with auditory discrimination and attentional mechanisms, it is not surprising that several researchers have uncovered evidence linking noise exposure with deficits in reading. It is important to note at the onset that unlike chronic effects of noise on cognition, studies of reading and achievement confound chronic and acute noise exposure since they all have relied

upon archival records of achievement tests. As indicated in Table 7, however, the handful of studies of acute noise on intellectual achievement find few if any negative effects. This suggests, indirectly, that the community noise and achievement findings are probably caused by chronic and not acute exposure.

Two clusters of chronic noise associations with intellectual achievement are shown in Table 7. The first group of studies, conducted primarily by Wachs and colleagues, have explored the impacts of early exposure to noise in the home on infants and toddlers. Their work in general finds positive evidence that noise can interfere with normal cognitive development. The findings have been replicated and extended in longitudinal studies (see Wachs & Gruen, 1982, for an overview of this research program). Measurements of cognitive development affected by noise include mental representations of objects, use of objects as tools to achieve goals, and relating words to objects.

One major weakness in Wach's and other research on noise and young children (e.g., Heft, 1979) is reliance on observer ratings of noise exposure rather than actual measurement of physical sound levels. Recently, however Wachs (1988) has validated this measurement approach against decibel meter readings. Another finding that indicates that the effects are due to noise is that access to a secluded quiet room or shelter within the home largely ameliorates the associations between noise ratings and measures of cognitive development (Wachs & Gruen, 1982). Michelson (1968) has found the same buffering effect of a stimulus shelter with home noise levels on elementary school aged children's reading ability. These data on buffering effects of quiet, secluded study spaces in noisy homes raise the possibility, however, that some of the apparent effects of residential noise exposure on cognitive development could be due to residential crowding. It is obviously difficult to disentangle the ecological covariation between these two environmental conditions. Moreover, both of them appear to be associated with deficits in reading acquisition in young children (Evans et al., 1990).

The second group of studies in Table 7, has examined the association between chronic noise exposure at school and/or home with standardized measures of reading and other intellectual achievement tests. With two exceptions, the data

Table 7. Effects of noise on intellectual achievement

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Bronzaft (1981)	Reading.	Train. 6-8 dBA sound reduction in noisy classrooms.	(955) grades 2-6.	After sound reduction with insulation on noisy side of school, students' reading scores on noisy side of school were equivalent to those of students on quiet side of school. In the year before insulation, students on noisy side of school had worse reading scores than students on quiet side of school.
Bronzaft & McCarthy (1975)	Reading.	Train. 59-89 dBA.	(161) grades 2, 4, 6.	Students' reading scores lower on noisy side of school than on quiet side, especially in higher grades.
Cohen et al. (1973)	Reading.	Traffic and street. 55-66 dBA.	(54) grades 2-5.	Noise associated with greater reading deficits in children living in apartments for 4 or more years.
Cohen et al. (1980)	Reading and math.	Aircraft. 95 dBA peak.	(262) grades 3-4.	No noise effects.
Cohen et al. (1981)	Reading and math.	Aircraft. 95 dBA peak.	(163) grade 3-4, longitudinal.	No noise effects.
Cohen et al. (1981)	Reading and math.	Aircraft. 16 dBA sound reduction in noise-abated classrooms.	(163) grade 3-4, cross-sectional.	Noise abatement results in 3rd grade only. Third graders in noise-abated classrooms performed better in math than 3rd graders in non-abated classrooms; 3rd graders in noise-abated classrooms also performed better in reading, but not significantly so.
Cohen et al. (1986)	Reading and math.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	No noise effects.
Gottfried & Gottfried (1984)	BSID, OP, MS, TELD	Noise ratings: 1 = normal level voices in home for 15 min. period to 4 = noise level voices in home for more than half 15 min. period.	(130) 12 mon. infants tested every 6 mon. up to 42 mon.	Higher household noise associated with lower scores on OP at 12-18 mon., on TELD at 39 mon., on BSID at 18 mon., and on MS scores at 42 mon.
Green et al. (1982)	Percent reading below grade level.	Aircraft. 96.2 dBA peak.	(8,240) grades 2-6.	Greater percentage of noisy-school children read below grade level. Effects strongest in higher grades.
Lukas et al. (1981)	Reading and math.	Traffic and street. 70 dBA peak.	(2500) grades 3,6 (100 classes sampled).	Reading scores lower for 3rd and 6th graders in noisier classes. Math scores lower in students in noisier 3rd grade classes, but higher in 6th grade students in noisier classes.
		Ambient classroom and community. 45-75 dBA.		Inverse correlations between community noise and math and reading scores were similar to but less consistent than those between classroom noise and math and reading scores. There also was a synergistic effect of home and school noise on reading.

Table 7. *Continued*

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Wachs et al. (1971)	IPDS	Noise ratings: 1 = normal level voices in home for 15 min. period to 4 = noise level voices in home for more than half 15 min. period.	(102) ages 7, 11, 15, 18, 22 mon.	Higher household noise associated with lower IPDS scores.
Wachs (1978)	SB	Ratings of noise: same as Wachs et al. (1971).	(23) ages 2-3 yrs. longitudinal.	Higher household noise associated with poorer SB performance in boys, no significant effect in girls.
Wachs (1979)	IPDS	Ratings of noise: same as Wachs et al. (1971).	(31) ages 2-3 yrs. longitudinal.	Higher household noise associated with lower IPDS scores in boys and higher IPDS scores in girls.
Wachs & Gandour (1983)	IPDS	Ratings of noise: same as Wachs et al. (1971).	(100) ages 7, 11, 15, 18, 22 mon.	Higher levels of household noise associated with lower IPDS scores, particularly in fussy and irritable infants.
Michelson (1968)	Language, spelling, and math.	Home environment ratings. Scale unavailable.	(710) grades 1-5.	Noise associated with language and spelling difficulties. Noise not associated with math achievement.
Maser et al. (1978)	Reading and math.	Aircraft. 90 dBA peak.	(1917) grades 3, 5, 7, 10.	Noise associated with reading and math deficits in 7th and 10th graders, but only marginal effects on 5th graders. Children with lower aptitudes were most adversely affected by noise.
Acute noise				
Christie & Glickman (1980)	SPM	Recorded classroom noise. 40 and 70 dBA.	(156) grades 1, 3, 5.	Noise x Sex interaction: Boys performed better in noisy than in quiet conditions; girls performed better in quiet than in noisy conditions.
Johansson (1983)	Reading and math.	White noise. 51 dBA continuous, and 55-78 dBA intermittent.	(66) age 10 yrs.	Noise x Intelligence interaction on multiplication and reading performance. Above-average intelligence children solved more multiplication problems in noise than in quiet; below-average intelligence children showed the opposite trend, but noise effects were not significant. Below-average intelligence children tended to have poorer reading speed under noise; there was little difference in reading performance between noise groups with above-average intelligence.
Kassinove (1972)	Math.	Recorded child stories and music. 70-80 dBA.	(80) grades 3,6.	No noise effects on response latency, accuracy, or time-out from task.
Slater (1968)	Reading and math.	Ambient classroom noise, music, stomping and banging, tractor-mower, or quiet crossed with taped white noise. 45-90 dBA and 50-80 dBA white noise.	(263) grade 7.	No noise effects on speed or accuracy.

Table 7. *Continued*

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Weinstein & Weinstein (1979)	Reading.	Classroom: Ambient noise levels during early (noisy) and late (quiet) time of day. 47-60 dBA.	(60) grade 4.	No noise effects.
Zentall & Shaw (1980)	Math.	Taped noise from 2nd grade class. 64 and 69 dBA.	(48) grade 2 (hyperactive, normal controls).	Noise x Hyperactivity interaction: Hyperactive children performed marginally worse in high noise than in low noise; non-hyperactive children performed worse in low noise than in high noise conditions.

Note: BS = Bayley scales of infant development, OP = object permanence scale, MS = McCarthy scales of children's abilities, TELD = test of early language development, IPDS = Piagetian-type measure of infant psychological development, SD = Stanford-Binet test of intelligence, SPM = standard progressive matrix test.

converge on the conclusion of a relation between community noise exposure and reading ability. Several of the studies have good controls for sociodemographic characteristics in the samples and some have screened out children with auditory deficits. Moreover, Green et al. (1982) found a dose response function between noise exposure and reading deficits. Furthermore, the effects in the Bronzaft studies (Bronzaft, 1981; Bronzaft & McCarthy, 1975) cannot be attributed to self-selection. Children were not assigned in any systematic manner to classrooms on the noisy or quiet side of a building located next to elevated train tracks. On the other hand, all of the studies except for Bronzaft (1981) and Cohen et al. (1981) are cross-sectional and neither of these longitudinal studies are prospective. The Bronzaft (1981) findings are particularly important because they indicate that classrooms on the side of an elementary school near elevated train tracks that previously had lower reading scores in comparison to classrooms on the opposite side of the building (Bronzaft & McCarthy, 1975) no longer differed in reading scores following noise insulation in the schools and on the tracks.

The two studies that have not found reliable noise effects on reading may have poor statistical power. Both Cohen et al. (1980; 1986) and Moch-Sibony (1984) tested children from different schools, with different teachers, and in the former case from different school districts. In addition, both restricted their analyses to children from lower grades and did not attempt to tease out the

effects of noise on children of differing ability.

As indicated in several of the citations in Table 7, children in higher grades appear to be more negatively affected by noise exposure on reading than their younger counterparts (cf., Cohen et al., 1973; Green et al., 1982; Lukas et al., 1981; Maser et al., 1978). Children who have lower aptitude or other difficulties may be more vulnerable to the harmful effects of noise on reading (Maser et al., 1978). We also noted earlier several distraction studies indicating more disruptive effects on children with various learning deficiencies. Finally, Lukas and colleagues (1981) uncovered a significant synergistic effect of home and school noise exposure on reading scores.

Summary

Acute noise exposure appears to have little effect on reading and other intellectual activities. During early development, however, residential noise appears to delay cognitive development. In addition, chronic exposure to noise has been associated with reading deficits in seven out of nine studies, particularly for children in higher elementary school grades. There is also evidence that children with lower aptitude and those who also live in noisier homes appear more susceptible to the association of chronic noise exposure at school with reading deficits. The latter trend is interesting to consider in light of attentional data also showing more negative effects of noise exposure on children with pre-existing cognitive deficits.

DISCUSSION

Overview

We know with a good deal of certainty that chronic exposure to noise is associated in children with modest elevations of resting blood pressure, attentional deficiencies, and deficits in reading. Other effects suspected from chronic noise exposure include diminished task motivation, deficits in auditory discrimination, shifts in resistance to auditory distractors, poorer memory when high information processing demands are present, and deficits in infant cognitive development. The latter group of suspected effects include inconsistent data in some cases (auditory discrimination, resistance to distraction) or trends that have only been uncovered in one or two studies (motivation, memory, infant cognitive development). Tables 1-7 provide summary information that forms the bases for these conclusions.

Two major methodological shortcomings are prominent in the literature we have reviewed. Most critically, there is a total lack of prospective, longitudinal designs in this research area. Prospective, longitudinal studies are the strongest, quasi-experimental designs that can be applied in field studies and help deal with the host of threats (e.g., self-selection, confounding third variables) that plague correlational designs (see Cohen et al., 1986; Evans & Lepore, in press, for further discussion of methodological problems in field studies of environmental stressors). Such prospective studies must include well matched comparison groups and collect important personal data known to relate to outcomes of interest. Besides their utility as potential control variables in nonexperimental study designs, background variables can enhance statistical power by reducing unexplained variance in the outcome measure of interest. Studies on cardiovascular outcomes, for example, need to collect data on family history of hypertension. Research on reading should collect information on parental education levels and child's intelligence. Prospective, longitudinal designs will have to contend, however, with the potential interfering effects of selective attrition. As documented earlier, Cohen and his colleagues (1981), in one of only two longitudinal studies of noise and children, found that a year later children with the highest levels of blood pressure in their initial

cross-sectional analysis of quiet and noisy schools had moved out of the area. No such selective attrition was found among children in quiet schools.

The second major methodological shortcoming in nonauditory noise research and children has been lack of precision in two aspects of procedural conditions during testing. Testing conditions must be uniform and quiet. Reliance on archival measures of reading, for example, confounds acute with chronic noise exposure since ambient noise sources are likely to be present during the conduct of achievement tests. Testing must occur under quiet conditions in order to determine whether chronic noise affects reading or some other outcome of interest. More thorough audiometric screening is needed in nonauditory studies of noise and children to insure that the effects are not due to hearing loss.

Ecological Perspective

The purpose of this section is to outline some major conceptual shortcomings in the existing work on the nonauditory effects of noise on children and to lay out a preliminary research agenda. An ecological perspective (Bronfenbrenner, 1979) would significantly advance our understanding of this topic. Such a perspective includes greater attention to temporal issues plus the social and environmental contexts in which chronic noise exposure occurs. It also entails examination of the underlying, mediational processes that may link some of the psychophysiological, motivational, and cognitive processes related to chronic noise exposure.

Temporal parameters

Foremost, there has been a severe lack of developmental analyses, except in a few reading studies and in some of Wach's work on infant development in the home environment (see Table 7), of the effects of chronic noise on children. Developmental research approaches are critical in noise studies because it is highly likely that noise has differential impacts on physiological, cognitive and motivational processes as a function of developmental status. Consider for example reading acquisition. It is well established that reading acquisition depends upon the development of certain language competencies (e.g., phonological awareness) that are age

dependent (Mann & Brady, 1988). Noise exposure prior to or following the development of phonological awareness may not affect reading acquisition in the same way as noise exposure during the critical period of phonological awareness learning. Unless a developmental approach is added to noise research, such questions cannot be addressed.

A related but distinct conceptual limitation has been neglect of temporal parameters such as age at time of exposure and history of exposure to noise. For example, several studies on resistance to distractors from noise indicate the effects are contingent upon noise exposure history (see Table 5). Children exposed to ambient noise levels for shorter periods of time appear to be more resistant to the distracting properties of noise (see Table 5). These findings could relate to work on motivational deficiencies from prolonged noise exposure. Perhaps children attempt to filter out noise during early periods of exposure but eventually give up on this strategy. Duration effects could also relate to the specificity of resistance to auditory distractors. It would be interesting, for example, to investigate children's ability to filter out aircraft noise versus white noise or irrelevant speech, as a function of length and type of chronic noise exposure.

Unfortunately, we cannot disentangle age effects from exposure duration effects. For example, the apparently stronger linkages between chronic noise exposure and reading scores among older children (see Table 7) could be a function of a critical period of exposure or the result of longer, cumulative adverse impacts. Related to this latter option, we know nothing at this stage about the long-term effects of early childhood exposure to noise. What happens in later childhood or adolescence to children who spend all or part of their early years attending school or living near an airport or busy street?

Context

Greater attention to the ecological context in which chronic noise exposure occurs may prove fruitful for future research on noise and children. This ecological context might include more ecologically valid noise exposure estimates, attention to the indirect effects of noise on children via adult caregivers, and measurement of other social and environmental conditions covarying with chronic noise exposure. With one

exception (Lukas et al., 1981) none of the field studies of noise and children have attempted to calculate overall noise exposure. It may be recalled that Lukas and colleagues found a synergistic effect of home and school noise exposure on reading.

Furthermore, the noise estimates that researchers have relied upon do not take into account children's mobility, exposure to noise sources in the home, or the attenuation properties of the structures they inhabit.

Nearly all of the work on noise and children involves comparisons between noisy and quiet settings. With one exception, Green et al. (1982), there is no information on dose response functions. Besides its evidentiary value, dose response curves would have public policy importance. We currently are unable to provide clear statements about what level of noise is harmful for children or to say what the efficacy would be of providing specific sound attenuation interventions.

Not only are children attending school or residing in homes in noisy areas exposed to noise but so are their principal caregivers. The behaviors of caregivers in noisy settings could indirectly influence children's responses to noise (Bronfenbrenner, 1979). For example, perhaps parents in noisy homes do not speak to their children or read to them as often as parents in quieter neighborhoods. Classroom observations and teachers' self-reports indicate that aircraft or train noises interrupt teacher lecturing (Crook & Langdon, 1974; Kyzar, 1977; Moch-Sibony, 1974), in one study causing a 10% reduction in total teaching time (Bronzaft & McCarthy, 1975). It is also well documented that teachers in noise-exposed classrooms report greater annoyance and fatigue during the school day in comparison to teachers from quiet classrooms (Crook & Langdon, 1974; Ko, 1979; 1981; Sargent et al., 1980). Therefore some of the adverse effects of noise on child development could be mediated through the negative impacts of noise on the child's primary caregivers. Parents and teachers may have less patience and energy to devote to children because of the adverse effects of noise on themselves. More directly, noise may alter the manner in which parents and teachers instruct children, altering reading or speaking patterns. Recent data indicate that parent-child interactions may be affected by household noise levels. Parents from noisier homes appeared less

interested in their children's activities and talked less with their children (Wachs, 1989; Wachs & Camli, 1991). Controls for education levels of the mother did not change these findings.

Ambient noise exposure rarely occurs in isolation of other social and environmental problems. Noisy environments frequently covary with crowding and pollution and are often part of the fabric of poverty, including substandard housing, conflictual households and various other psychosocial strains. Although the ecological covariation of noise with other adverse environmental and social factors makes it difficult to isolate the effects of noise on children, we should be mindful that the harmful effects of noise may be amplified by the context in which noise is often embedded. It may be precisely those children who develop under such impoverished physical and social circumstances who are most vulnerable to the harmful effects of noise (Bronfenbrenner, 1979; Evans et al., 1990). We have recently found among adults, for example, that the negative effects of residential crowding on psychological distress are significantly worsened by chronic strains associated with poverty (e.g., insufficient utilities, poor housing quality, financial insecurities) (Lepore et al., 1991).

Noise levels may also operate within a context of important individual differences among children. There is some evidence that some children are more at risk for adverse noise effects on cognitive development. Less intelligent children's math and reading performance appears more sensitive to noise exposure (Johansson, 1983; Maser et al., 1978). Studies of young children and infants suggest greater susceptibility to chronic noise-related problems among boys in comparison to girls (Wachs, 1978; 1987; 1989). On the other hand, girls may be more distracted by acute noise exposure (Christie & Glickman, 1980; Hambrick-Dixon, 1988). Cognitive performance during acute noise appears to be disrupted more by noise for individuals with pre-existing learning deficits (cerebral palsy, learning disabled).

In addition to alerting researchers and policy makers to the potential of subgroups of children at high risk for negative effects of noise, these findings also have another important implication. Some of the small or even conflicting nonauditory effects of noise reviewed herein may be conservative estimates of noise effects since they by and large have not examined interactive effects.

While in some cases there may be little if any overall noise effects on children, it would be erroneous to conclude from such data profiles that noise is an inconsequential environmental problem for children. There may be large segments of the child population whose development may be significantly compromised by noise exposure early in life.

Mediational processes

Another area of future research that might emanate from an ecological perspective on noise and children is greater scrutiny of the potential interplay among the various psychophysiological, cognitive, and motivational processes that appear to be affected by chronic noise exposure. Cohen and his colleagues (1973) examined Deutsch's (1964) hypothesis that children chronically exposed to noise may learn to tune out auditory stimuli indiscriminantly and thus not pay sufficient attention to speech. They found that children from noisier apartments were deficient in auditory discrimination. Of particular interest, this deficiency significantly accounted for the poorer reading abilities of the noise-exposed children. This study stands alone as the only analysis of an underlying process to explain how noise affects children.

Given the findings (see Table 4) that noise can mask speech and evidence that speech perception and other linguistic skills such as phoneme awareness are critical precursors to reading acquisition (Mann & Brady, 1988), more work is called for on the effects of chronic noise exposure on psycholinguistic processes and their potential mediating link with reading. Other pathways warranting further investigation include those between chronic noise exposure, motivation, attention, and reading.

There are also plausible interconnections among chronic noise exposure and several of the cognitive processes we have reviewed. For example, people chronically exposed to noise may become more resistant to the distracting effects of acute noise exposure during a task because they can ignore or filter out auditory distractors. This ability may occur as a result of learning to tune out or filter auditory sounds. Thus one would expect a relation between the ability to ignore auditory distractors and deficits in auditory discrimination associated with chronic noise exposure. Analogously, we would expect a mediational pathway

between chronic noise exposure, attentional focusing and deficits in incidental memory performance.

Thus rather than only treating different outcome variables such as reading, attentional processes, and resistance to distraction as separate correlates or effects of noise exposure, more thought and careful analyses are required to investigate how these variables may form causal links to one another. In other words, both the direct and indirect pathways of the nonauditory effects of noise on children need to be investigated. From a theoretical and public policy perspective, this is perhaps most crucial in the case of reading. Although stronger data on the adverse effects of chronic noise exposure on reading would be valuable from an evidentiary point of view, what is of paramount importance now is a shift in focus to explanations of why and how chronic noise adversely influences reading acquisition.

There may also be some potent interplay among psychophysiological processes and some of the cognitive strategies apparently influenced by chronic noise exposure. For example, presumably it takes some effort to tune out or ignore noise. Experimental data as well as field studies with adults indicate that cognitive efforts to maintain task performance during noise come at a price of heightened sympathetic arousal (Tafalla & Evans, 1993; Welch, 1979). When performance suffers under noise, slight or no sympathetic arousal is apparent. However, if performance is maintained under noise which is possible except under tasks of very high load demands on attention and working memory (Cohen et al., 1986; Smith, in press), then indices of sympathetic arousal should be substantially elevated during noise exposure.

The associations between chronic noise exposure in children (see Table 1) and heightened blood pressure raise several important questions about mechanisms. For example, are blood pressure elevations caused by repeated sympathetic arousal induced by the distracting and interfering properties of community noise conditions? Alternatively, are the elevations mediated by adrenocortical activity and thus primarily indicative of chronic stress? To our knowledge, no analyses of various psychoneuroendocrine pathways between noise and blood pressure elevations have been investigated. Given the central role of cognitive appraisal in psychological

stress, it would also behoove researchers to examine whether psychosocial factors such as perceived control, self-confidence to ignore/tune out noise, or annoyance, moderate the effects of noise on blood pressure and other psychophysiological processes among children.

Another fruitful area of psychophysiological research would be to investigate the potential role of chronic noise exposure in cardiovascular reactivity. Individual differences in reactivity to standard psychosocial elicitors of stress (e.g., mental arithmetic) may be predictive of cardiovascular disease (Krantz & Manuck, 1984; Matthews et al., 1986). Research on cardiovascular reactivity in both adults and children has ignored the potential etiological role of chronic exposure to environmental stressors. More detailed analyses, focusing on possible behavioral toxicological effects of in utero or neonatal noise impacts are also called for. This is especially pertinent in light of contemporary medical practices such as ultra sound monitoring or placement of premature infants in neonatal intensive care units.

Large numbers of children both in America and, in rapidly growing numbers in the Third World, are being exposed to levels of ambient noise that are not only a threat to hearing but may have harmful effects on physiological and cognitive development. The potential for harmful effects from chronic noise exposure on children's development is great; what we know with certainty about the problem is, unfortunately at the moment, insufficient. At the same time, there is a foundation of evidence clearly suggesting potentially harmful effects from chronic noise exposure among children. We also have enough data on hand to formulate preliminary models of underlying, mediating mechanisms that could account for the effects of noise. It is also clear that more longitudinal work with prospective designs is crucial to definitively demonstrate the relationships between chronic noise exposure and children's development. Such designs afford stronger internal validity given the impossibility of randomly assigning children to varying community noise levels. Longitudinal designs allow us to examine changes in behaviors over time plus provide the opportunity to examine whether self-selection has occurred prior to noise exposure.

ENDNOTE

This article is based in part on earlier presentations at the Fifth International Congress on Noise as a Public Health Problem, Stockholm, Sweden and A Strategy for Noise Prevention in the 90's, American Speech and Hearing Association, Washington, DC. Preparation of this article was partially supported by the National Heart Lung and Blood Institute, RO1 HL47325-01A1, the Nordic Noise Council, and the Swedish Environmental Protection Board.

Research Article

CHRONIC NOISE AND PSYCHOLOGICAL STRESS

Gary W. Evans,¹ Staffan Hygge,² and Monika Bullinger³¹Cornell University; ²Royal Institute of Technology, Gävle, Sweden; and ³University of Munich

Abstract—This article illustrates the value of incorporating psychological principles into the environmental sciences. Psychophysiological, cognitive, motivational, and affective indices of stress were monitored among elementary school children chronically exposed to aircraft noise. We demonstrate for the first time that chronic noise exposure is associated with elevated neuroendocrine and cardiovascular measures, muted cardiovascular reactivity to a task presented under acute noise, deficits in a standardized reading test administered under quiet conditions, poorer long-term memory, and diminished quality of life on a standardized index. Children in high-noise areas also showed evidence of poor persistence on challenging tasks and habituation to auditory distraction on a signal-to-noise task. They reported considerable annoyance with community noise levels, as measured utilizing a calibration procedure that adjusts for individual differences in rating criteria for annoyance judgments.

Since the early 1970s, psychologists have contributed insights to the analysis of environmental problems (Ittelson, 1976). Current concerns focus on human perceptions of environmental risks (Vaughan, 1993; Wandersman & Hallman, 1993) and the role of the physical environment in human health and well-being (Baum & Fleming, 1993). The concept of psychological stress has proven a useful heuristic to conceptualize human responses to suboptimal environmental conditions (Cohen, Evans, Stokols, & Krantz, 1986; Evans & Cohen, 1987). The present article provides evidence that chronic noise exposure is associated with psychophysiological, cognitive, motivational, and affective indices of psychological stress.

Laboratory studies have shown that acute noise degrades complex task performance (Smith & Jones, 1992) and elevates neuroendocrine and cardiovascular markers of psychological stress (Evans & Cohen, 1987). Chronic noise is associated with elevated cardiovascular functioning among children (Cohen et al., 1986) and is consistently correlated with reading deficits among elementary school children (Evans & Lepore, 1993). Experimental exposure to uncontrollable noise produces learned helplessness (Glass & Singer, 1972; Seligman, 1975), and long-term exposure to community noise may contribute to helplessness among children (Cohen et al., 1986).

The present study extends these earlier findings in several respects. This is the only study to examine neuroendocrine indices of chronic stress among persons exposed to community noise. Without neuroendocrine markers, it is difficult to interpret children's elevated cardiovascular reactions to chronic noise exposure as evidence of stress (Grunberg & Singer, 1990;

Krantz & Falconer, 1995). Furthermore, although resting cardiovascular levels are an important indicator of health, cardiovascular reactivity to acute stressors may contribute more to the etiology of coronary heart disease (Krantz & Manuck, 1984).

Several measures of human performance were also assessed in the present study. Speech perception was examined because of its relevance to noise and its potential role in reading acquisition (Mann & Brady, 1988). We also examined two attention tasks, choice reaction time and visual search. There is some evidence of deficits in both working memory (Hamilton, Hockey, & Rejman, 1977) and long-term memory (Hygge, 1993) during acute noise exposure. No research has examined the generalizability of these types of findings to persons chronically exposed to noise.

Many prior studies have uncovered associations between ambient noise levels and reading deficits (Evans & Lepore, 1993). Unfortunately, all of these studies have relied on archival reading achievement scores, thereby confounding chronic and acute noise exposure. We administered a standardized reading test under carefully controlled, quiet conditions.

Children chronically exposed to noise (Cohen et al., 1986) and to crowding (Rodin, 1977) suffer increased vulnerability to learned helplessness. We designed a conceptual replication of these earlier findings, adapting Glass and Singer's (1972) after-effects paradigm for use with children. Numerous acute stressors reliably decrease persistence on challenging puzzles presented immediately after stressor exposure (Cohen, 1980; Glass & Singer, 1972). This paradigm, to our knowledge, has never been adapted for children or been used to examine chronic stress and motivation.

Although adults living in noise-impacted communities react with annoyance (Evans & Cohen, 1987), very little is known about children's affective responses to noise. We investigated this issue in two ways. First, we examined children's annoyance to a series of standardized auditory stimuli, as well as to community noise sources. This procedure enabled us to examine both raw and calibrated annoyance ratings. Calibration may enhance the sensitivity of annoyance scales given large individual differences in response criteria for assessing annoyance (Berglund & Nordin, 1990). The second way we investigated children's affective reactions to chronic noise exposure was by assessing quality-of-life ratings. Quality of life can be assessed accurately in young children (Bullinger, von Mackensen, & Kirchberger, 1994), indexing perceived physical, psychological, social, and daily functioning.

Summarizing, we employed the concept of psychological stress as a heuristic to conceptualize human responses to suboptimal environmental conditions. Our analyses focused on psychophysiological, cognitive, motivational, and affective processes in relationship to chronic noise exposure among young children.

METHOD

Subjects

Participants were 135 third and fourth graders (mean age = 10.78 years) living either in a high-noise-impact urban neighborhood (24-hr Leq = 68.1 dBA; peak = 79.8 dBA) surrounding the Munich International Airport or in a quiet urban neighborhood (24-hr Leq = 59.2 dBA; peak = 69.0 dBA) in Munich. An increase of 10 dBA is experienced as approximately twice as loud. Leq is an unweighted average of sound pressure intensity. Children in the quiet, comparison areas were matched to the children in the noise-impacted area according to socioeconomic status. Households did not differ in type of occupation, $\chi^2(4, N = 116) = 4.96$; parental education, $t(122) = 1.58$; or family size, $t(122) = 1.10$. All of the children in this study first passed an audiometric screening to ensure that none had hearing loss.

Dependent Measures

Psychophysiological

Blood pressure was measured with an automated blood pressure monitor (A&D Digital, UA 751) while the child was seated comfortably. Twelve-hour overnight urinary epinephrine and norepinephrine were assayed with high-performance liquid chromatography with electrochemical detection (Riggin & Kissinger, 1977), and cortisol was measured with a radioimmunoassay, iodine¹²⁵ (Baxter Travenol Diagnostics, Cambridge, Mass.). Sample volumes were determined, and a small amount of urine was randomly extracted and frozen at -70°C . Half of the extracted urine was also pH adjusted to further inhibit oxidation of catecholamines. See Grunberg and Singer (1990) and Lundberg (1984) for more details on utilizing urinary neuroendocrine measures as indices of chronic stress.

Cognitive

Cognitive measures included indices of attention, memory, and reading.

Attention. A signal-to-noise measure assessed speech perception against a noise background. Each child listened to a story at his or her preferred volume. This volume level defined continuous background noise (road traffic, aircraft, or broadband) played throughout the story. At fixed, random intervals, the storyteller's voice dropped 10 dBA, and the child readjusted the story volume to a comfortable listening level.

An embedded figures task required the children to search for any one of five target figures contained within complex line drawings.

In a simple choice reaction time task, the children were presented with random sequences of red and green lights and were instructed to press the key labeled "red" or "green" to indicate the color of each light. Two 8-min sequences were run. The first session was conducted in silence and the second one in aircraft noise (80 dBA Leq).

Memory. Each child read an interesting text. Random, intermittent broadband noise bursts (peak dBA = 80) were pre-

sented throughout the 12-min period. A day later, the child's long-term recall for the text was assessed.

Working memory span was assessed by presenting consonants at the rate of one per second. At random intervals, the sequence was stopped and the child was requested to recall, in order, as many consonants as possible. Accuracy was defined as correct recall of the consonants in serial position (Hamilton et al., 1977).

Reading. Children read paragraphs as well as word lists on the Biglmaier (1969) Reading Test (a valid and reliable German standardized test) under quiet conditions. Standardized scoring criteria were applied to each subscale.

Motivation, annoyance, and quality of life

Motivation. After reading the long-term memory text under noisy conditions, the children were given two line-tracing puzzles adapted from Glass and Singer's (1972) aftereffects paradigm. The puzzles consisted of animal names connected together by lines. Children "traveled" to each animal via the connecting lines but without lifting their pencils or retracing any line. They attempted the first puzzle until they solved it or gave up, and then moved on to the second puzzle. The initial puzzle was insoluble, and the index of motivation was the number of attempts to solve this puzzle. The second puzzle was soluble. The order of the two puzzles was deliberately fixed so that each child would experience success following initial failure on the first puzzle. All children solved the second puzzle. The task lasted 10 min. Attributions for failure on the initial puzzle were also assessed. These data are not included here because of space limitations.

Annoyance. The children provided magnitude estimates of noise annoyance (0 = not at all annoying; 100 = the most noise one could withstand without putting one's hands over one's ears) by moving their fingers along a vertical graphic scale. They were trained how to use this scale by first jumping as far as possible, which was designated as 100. They then jumped distances equivalent to magnitudes of 50, 25, 75, and 10.

Four-s noise bursts were randomly presented over headphones at 42, 54, 66, 78, and 90 dBA Leq. Broadband noise, aircraft noise, and road traffic noise were presented in separate sets. The annoyance rating for each noise burst was indicated on the vertical graphic scale from 0 to 100. The children also indicated how annoyed they were with community noise levels. Both Bandura and Schunk's (1981) original scale development and our own pilot work indicate high reliability for this magnitude estimation procedure with young children.

Nine uncalibrated noise ratings were summed to provide the community noise rating for each child. Calibrated scores were individually adjusted by the slope of the regression line fitting each child's annoyance ratings of the broadband-noise standard stimuli to his or her community noise estimates. For more details on calibration scoring procedures, see Berglund and Nordin (1990).

Quality of life. Quality of life was assessed by the KINDL, a valid and reliable index of the four principal domains of qual-

ity of life (physical, psychological, social, functional daily life; Bullinger et al., 1994).

Procedure

Testing occurred in a climate-controlled, sound-attenuated trailer at the children's school. Forty-eight-hr outdoor noise levels were monitored at the trailer 6 m above ground with a B&K Model 4426 Sound Meter.

Experimental tasks were conducted in fixed order on 2 consecutive days. Children were run individually in booths, with an experimenter sitting across a small table from each child. On Day 1, each child was first taught the magnitude estimation procedure (jumping), as described. Then an initial blood pressure reading was taken, and the child completed a brief mood scale. Then the following tasks occurred: noise annoyance; audiogram; blood pressure; mood scale; signal-to-noise measure; blood pressure; long-term memory text with noise, accompanied by blood pressure readings every 4 min; Glass and Singer aftereffects measure (line-tracing puzzles); and blood pressure. Total testing time for Day 1 was 85 min.

At the end of Day 1, parents were given a urine specimen bottle and instructions for collecting the 12-hr overnight sample. Parents were requested to collect in the container all urine the child voided that same night and the next morning between 20:00 and 8:00. This container was kept refrigerated and contained a preservative.

On Day 2, parents brought back the urine specimen container. Testing began with an initial blood pressure reading, followed by a mood scale and then a brief interview, a blood pressure reading, recall of the prose text from the day before, the standardized German reading test, a blood pressure reading, the embedded figures task, the test of working memory, another blood pressure reading, and finally the reaction time task, accompanied by blood pressure readings every 4 min. The child was then given a gift and provided the opportunity to ask questions about the study. Total time for Day 2 was 87 min.

The KINDL was administered at home prior to the laboratory testing.

RESULTS

Psychophysiological

Neuroendocrine

Overnight resting levels of urinary catecholamines were significantly different between the children chronically exposed to

aircraft noise and those unexposed: $t(120) = 2.89, p < .025$, for epinephrine and $t(120) = 3.43, p < .001$, for norepinephrine. (All statistical tests are two-tailed unless otherwise indicated.) As shown in Table 1, resting, baseline adrenomedullary neuroendocrine levels were elevated in association with chronic exposure to high levels of community noise. There was, however, no significant relationship between chronic exposure to aircraft noise and cortisol levels, $t(120) < 1.0$.

Baseline cardiovascular

There was a marginally significant relationship between noise exposure and baseline systolic blood pressure, $F(1, 109) = 3.03, p < .08$. (Degrees of freedom vary throughout because of missing data and in the case of blood pressure readings, because some readings were clearly incorrect.) Baseline diastolic blood pressure was unrelated to noise exposure, $F(1, 109) < 1.0$. Baseline measures were calculated by taking the average of three resting indices from Day 1 and three resting measures from Day 2. On each day, an initial resting blood pressure reading was taken to help desensitize children to the procedure. This initial reading is not included in the results reported here. The blood pressure analyses include a covariate (ponderosity) for body fat.

Cardiovascular reactivity

There was significantly lower reactivity in systolic blood pressure among children chronically exposed to aircraft noise in comparison to their quiet-community counterparts, $F(1, 109) = 15.62, p < .001$ (see Table 1). Diastolic reactivity was unrelated to chronic noise conditions, $F(1, 109) < 1.0$. Cardiovascular reactivity was calculated by subtracting the resting baseline index from the initial blood pressure reading during the prose reading for the long-term memory task.

Cognitive

Attention

As shown in Table 2, children from noisy communities chose a lower signal-to-noise ratio than did those from quiet communities, $t(103) = 1.78, p < .05$ (one-tailed). The type of background noise (road, aircraft, broadband) did not interact with the main effect of community noise level. Noisy children's habituation to auditory distractors generalized across different types of noise. Preferred volume level for the signal (story reading) under quiet conditions was equivalent between the two groups, $t(103) < 1.0$. The two noise groups did not differ in

Table 1. Psychophysiological measures

Variable	Quiet communities	Noisy communities
Epinephrine	368.62 ng/hr	526.36 ng/hr
Norepinephrine	766.22 ng/hr	1,108.82 ng/hr
Cortisol	3.62 μ g/hr	3.75 μ g/hr
Resting diastolic blood pressure	63.56 mm Hg	63.39 mm Hg
Resting systolic blood pressure	100.73 mm Hg	102.65 mm Hg
Reactivity diastolic blood pressure	-0.71 mm Hg	-0.34 mm Hg
Reactivity systolic blood pressure	1.66 mm Hg	-3.31 mm Hg

Chronic Noise and Psychological Stress

Table 2. Cognitive measures

Variable	Quiet communities	Noisy communities
Signal/noise	10.87 dB	6.81 dB
Embedded figure (number correct: 0-12)	5.60	6.10
Reaction time (quiet conditions)	440.7 ms	450.0 ms
Reaction time (noisy conditions)	438.0 ms	454.0 ms
Long-term recall (number correct: 0-25)	5.76	4.54
Reading (number of errors)		
Text	41.30	50.80
Word recognition	4.57	7.10

performance on the embedded figures task, $t(131) < 1.0$, nor in reaction times either under quiet ($t(108) < 1.0$) or under noisy ($t(108) < 1.0$) testing conditions.

Memory

On the long-term recall task, children from noisy communities performed worse than their counterparts, $t(130) = 2.13, p < .05$. There were slight reductions in working memory span among children chronically exposed to noise. Only one of these differences was statistically significant (the fifth serial position from the last item presented).

Reading

As shown in Table 2, children from noisy communities had significantly more errors on the text subscale of the German standardized reading test than children from quiet communities, $t(127) = 2.02, p < .05$. On the word list subscale, children from the noisy and quiet areas differed on the most difficult section of the test, $t(125) = 2.10, p < .05$. The two groups did not differ on the easy and intermediate portions of the test. Children from the two groups completed equivalent portions of both the prose and the word list tests.

Motivation, Annoyance, and Quality of Life

Motivation

Children from noisy communities persisted less than children from quiet communities on the insoluble puzzle in the aftereffects task, $t(130) = 2.35, p < .02$ (see Table 3).

Annoyance

Children living in noisier areas were significantly more annoyed by the noise in their communities, as indexed by calibrated community measures, $t(132) = 2.17, p < .05$. The raw, uncalibrated scores showed the same trend.

Quality of life

As can be seen in Table 3, trends on the KINDL index were generally in the expected direction, but only the difference on the psychological subscale proved statistically significant, $t(124) = 2.47, p < .01$.

DISCUSSION

This article demonstrates the value of integrating psychological principles into the environmental sciences. Psychophysiological stress processes linked to coronary heart disease; central cognitive processes, including speech perception, memory, and basic reading skills; motivation; and emotional affect are all associated with chronic exposure to noise among children.

Our data reveal a link between chronic exposure to noise in the community and elevated neuroendocrine markers of stress, along with marginally increased resting levels of systolic blood pressure. Similar small increments in blood pressure have been noted previously (Cohen et al., 1986), but these are the first data on neuroendocrine markers of chronic noise exposure. We also reveal differential cardiovascular reactivity in response to task demands as a function of chronic environmental stress. Our pattern of psychophysiological stress findings (elevated baseline indices, diminished reactivity to challenge) is potentially quite important to consider in light of theories about stress and disease. Chronic stressor exposure, particularly exposure to stressors unamenable to instrumental control, may deplete coping capacity, rendering the organism less able to mobilize resources when needed to respond to acute challenges (Lepore & Evans, in press). At the same time, chronically elevated baseline indices of neuroendocrine and cardiovascular functioning

Table 3. Motivation, annoyance, and quality-of-life measures

Variable	Quiet communities	Noisy communities
Motivation (number of attempts to solve insoluble puzzle)	6.77	5.48
Calibrated annoyance (broadband noise equivalents)	62.49	67.47
Quality of life ^a		
Psychological (11-55)	30.20	27.85
Physical (9-45)	26.88	26.91
Social (9-45)	26.42	26.06
Functional (11-55)	30.04	29.33

^aThe higher the score, the higher the quality of life.

can cause physical damage directly via changes in hemodynamics and arterial tissue structure and indirectly via suppressed immune functioning (Cohen, Kessler, & Gordon, 1995).

Several cognitive processes are associated with community noise levels. Prior studies have shown correlations between ambient noise exposure and reading levels (Evans & Lepore, 1993). We demonstrated this association with a standardized reading test administered under quiet, controlled conditions. All prior studies have utilized archival reading records of tests administered under ambient testing conditions in school and thus have confounded chronic levels of noise exposure with acute levels during the testing periods. An important policy question raised by our data is, once children fall behind in reading skills because of noise exposure, do these deficits persist, or continue to widen, with continued noise exposure? We also do not know whether noise-related reading deficits are reversible should children change their residence or if extensive sound attenuation is installed in buildings where the children spend most of their time (i.e., school, home).

The cognitive data reveal a mixed pattern of results. Long-term memory was worse among the schoolchildren from noisy communities. Asked to recall information from an interesting text they had read the day before, they performed less accurately than children from quiet communities. Similar trends have been shown in laboratory research on acute noise (Hygge, 1993). Chronic noise exposure may diminish working memory span, although the effects appear quite small.

Neither the embedded figures task nor the reaction time task revealed any associations with noise exposure. Both of these results replicate studies of acute noise (Broadbent, 1979; Smith & Jones, 1992).

Children chronically exposed to noise were less sensitive to distracting, background noise during a speech perception task than were children from quiet neighborhoods. The noise-exposed children consistently chose a lower signal-to-noise ratio when readjusting a speaker's voice against noisy background conditions. Moreover, this perceptual adaptation generalized across different noise sources. Broadband noise, road traffic noise, and aircraft noise all revealed the same pattern. Under quiet conditions, preference for volume level of the speaker's voice was the same for children from quiet and noisy neighborhoods. These perceptual adaptation findings are consistent with prior work suggesting that children cope with chronic noise exposure by tuning out auditory stimuli (Cohen et al., 1986).

Overall, the cognitive data add to the growing list of studies indicating selective impairments in cognitive functioning among children reared under poor environmental conditions. In young children, more complex, higher order skills, such as reading, problem solving, and comprehension of difficult materials, appear vulnerable to adverse environmental conditions (Cohen et al., 1986; Evans & Cohen, 1987; Wachs & Gruen, 1982). The perceptual adaptation findings also raise important questions about the long-term consequences of children's coping mechanisms. Children may cope with adverse environmental conditions by developing cognitive strategies (e.g., tuning out ambient noise) that have consequences for language acquisition and speech processing.

We adapted Glass and Singer's (1972) stressor aftereffect

paradigm to measure potential motivational impacts of chronic stressor exposure on the children. Children from noisy communities exhibited less persistence in task performance when challenged. These data conceptually replicate earlier findings utilizing a different paradigm to assess motivational deficiencies in children chronically exposed to crowding (Rodin, 1977) and to noise (Cohen et al., 1986). The potential role of adverse physical or psychosocial conditions in early motivational development is an important and largely neglected topic of psychological inquiry.

Children living in noisy communities find the levels of environmental noise where they live annoying. Both raw and calibrated, the magnitude estimations of annoyance indicate this trend. These children also rated the quality of life, particularly psychological, in their communities as poorer than did the children from quiet communities.

Although we demonstrated that the noisy and quiet communities were similar with respect to socioeconomic status, the correlational design of our study precludes causal conclusions. Nonetheless, our preliminary evidence warrants more intensive follow-up, utilizing prospective, longitudinal field studies of chronic environmental stressors and children's health and well-being.

To summarize, our results reflect a general pattern of adverse psychological stress reactions associated with chronic exposure to noise among elementary-school-aged children. The children who were studied showed no apparent auditory damage during standard audiometric examination. Both neuroendocrinological and cardiovascular indices of chronic stress were elevated; long-term memory, speech perception, and standardized reading test scores indicate deficits; and children living proximate to a major airport reported more annoyance and a lower quality of life than did children in quiet communities. These data are sobering when one considers that more than 10 million American schoolchildren are exposed to comparable noise levels and that worldwide population exposure to noise is escalating exponentially with accompanying industrial development (Suter, 1991). Psychological principles have much to offer to the conceptualization and analysis of environmental problems.

Acknowledgments—We are extremely grateful to the families who cooperated with this research project. We thank Sylvia von Mackensen, Gerhard Helm, Gunnar Söderqvist, and Christian Wigren for their dedication to this project. Financial support for this research came from the Society for the Psychological Study of Social Issues, the National Institutes of Health (RO1 HL 4732 01A), the Nordic Noise Group, the Nordic Scientific Group for Noise Effects, the Swedish Environmental Protection Agency, and the German Research Foundation. Aftereffects of Stress on Human Performance and Social Behavior: A Review of Research and Theory

Sheldon Cohen
University of Oregon

A review of experimental and correlational studies of the aftereffects of stress on performance suggests that these effects occur as a consequence of a wide range of unpredictable, uncontrollable stressors including noise, electric shock, bureaucratic stress, arbitrary discrimination, density, and cold pressor. Moreover, these effects are not limited to a restricted range of stressful situations that involve a lack of predictability and controllability over a distracting stimulus, but they can also be induced by increased task demand. Interventions that increase personal control and/or stressor predictability are effective in reducing poststressor effects. There is also evidence for poststimulation effects on social behavior that generally involve an insensitivity toward others following stressor exposure. Studies of exposure to environmental stressors in naturalistic settings report effects similar to those found in laboratory settings. Several theories (e.g., psychic cost, learned helplessness, arousal) are examined in light of existing evidence. Although some theories receive more support than others, it is suggested that the reliability and the generality of poststimulation effects occur in part because of a multiplicity of causes.

The notion that continued exposure to a stressor may produce effects that appear only after stimulation is terminated has been central to the stress literature for a number of years. This assertion is derived principally from an adaptive-cost hypothesis which suggests that although humans can often adapt to extreme conditions, there are cumulative costs of adaptation. An early form of this hypothesis, which emphasized the biological costs of the adaptive process, was proposed by Selye (1956). He asserted that after prolonged exposure to a stressor, one's adaptive reserves are drained, resistance breaks down, and exhaustion sets in. Others (Basowitz,

Persky, Korchin, & Grinker, 1955; Dubos, 1965; Milgram, 1970; Wohlwill, 1966) make similar points in regard to poststressor effects on behavior. In the words of Dubos, "Although man is highly adaptable and can therefore achieve adjustments to extremely undesirable conditions, such adjustments often have . . . indirect effects that are deleterious" (1968, p. 139).

The early empirical work on the aftereffects of stress focused on stressor effects on physical and psychological health. For example, there are a number of studies on the cumulative effects of disease, malnutrition, and toxic chemicals on normal bodily functions (see Dubos, 1965). There is also an extensive research literature on the association between subjects' reports of recent life changes and subsequent changes in somatic and psychological health (cf. Dohrenwend & Dohrenwend, 1974).

It was only recently, however, that the first experimental studies of the postexposure effects of stressors on behavior were reported (Glass & Singer, 1972). The major emphasis

Preparation of this article was supported by National Science Foundation Grant BNS 77-08576 and by National Institute of Environmental Health Sciences Grant 1 R01 ES01764-01.

of Glass and Singer's research program was on determining whether the cognitive context of a stressor mediated performance on tasks administered immediately after stressor termination. Based on earlier research which demonstrated that the ability (or perceived ability) to predict or escape an aversive event reduced both the aversive quality of the stimulus (e.g., Corah & Boffa, 1970; Pervin, 1963) and the resultant physiological response (e.g., Champion, 1950; Corah & Boffa, 1970; Stotland & Blumenthal, 1964), they hypothesized that performance following stress exposure may be similarly mediated by stressor predictability and perceived control over stressor termination.

Glass and Singer's (1972) early work was strongly influenced by the adaptive-cost hypothesis. Specifically, they suggested that deleterious effects on performance following exposure to unpredictable, uncontrollable stressors should occur because the substantial effort required to adapt to these aversive events would leave one less able to cope with subsequent demands and frustrations. Since predictable and controllable stressors were viewed as considerably less aversive, adaptation to these stressors would presumably require less effort and therefore would be less likely to impair poststimulation performance. At the completion of their research program, Glass and Singer concluded that exposure to unpredictable, uncontrollable stressors produces poststimulation deficits in performance on a number of tasks and that the ability to predict and/or control the stressor ameliorates these effects. However, they also concluded that the adaptive process is not responsible for these poststress performance deficits.

Since the publication of the Glass and Singer (1972) book there have been over 30 published studies on the poststimulation effects of stressors on performance and social behavior. Moreover, a number of cognitive and motivational explanations for the aftereffects of stress have been offered and in some cases tested. This article reviews the existing laboratory and field research on the aftereffects of stress on performance and interpersonal behavior and outlines a number of possible explanations for these effects. The re-

search review is divided into five major sections. The first section examines studies that have attempted to determine whether there are effects of unpredictable, uncontrollable stress on performance following stressor termination. The second and third sections examine those studies that attempt to ameliorate poststimulation effects by providing subjects with a predictable version of the stressor and/or with control over the stressor. The fourth section describes studies of the poststimulation effects of stress on social behavior, and the fifth section reviews naturalistic studies of stress aftereffects. Finally, the theory review examines each of eight alternative explanations for poststress effects on performance and social behavior in light of existing data and reevaluates the adaptive-cost hypothesis.

Research Review

Aftereffects of Unpredictable and Uncontrollable Stressors

Studies reviewed in this section compare performance after exposure to an unpredictable, uncontrollable stressor with performance in an experimental control condition in which there was either a less intense form of the stressor or no stressor exposure. A number of these studies also included conditions in which the stressor was predictable and/or controllable. These conditions are not discussed here but are presented in later sections.

Noise. Glass and Singer (1972) reported five studies that examined poststimulation effects after exposure to unpredictable, uncontrollable noise (pp. 47, 50, 52, 55, 80). Their studies typically involved approximately 25 minutes of exposure to 108-110-dB (A) random-intermittent bursts of a broadband conglomerate noise made up of a number of fairly typical urban sounds. During noise exposure, the subject worked on simple cognitive tasks. Autonomic response was monitored during stressor exposure. Immediately after the noise exposure period, one or more of three measures were administered to the subject: the Feather (1961) tolerance for frustration task (studies reported in Glass & Singer, 1972, pp. 47, 52, 55), a proofreading

task (Glass & Singer, 1972, pp. 47, 50, 52, 55, 80), and the Stroop (1935) Color-Word task (Glass & Singer, 1972, p. 80).

The Feather measure requires a subject to work on two soluble and two insoluble line puzzles for 15 minutes. The subject can only work on one puzzle at a time and cannot return to a puzzle after moving on to the next. The puzzles are presented so that the first and third are insoluble and the second and fourth are soluble. The criterion measure (amount of tolerance for frustration) is the number of trials—puzzle cards—or amount of time spent on insoluble puzzles. The proofreading task involves correcting misspellings, grammatical mistakes, incorrect punctuation, transpositions, and typographical errors. Each subject is usually given between 8 and 15 minutes (although nothing is said about time), and the quality of performance is measured as the percentage of errors not found of the total number of errors that could have been detected at the point the subject was told to stop. In the Stroop task, task stimuli are the names of four colors (green, red, orange, and blue), each of which is printed in one of the other three colors. For example, the word *green* may be printed in red, orange, or blue. The four color words are presented randomly over a series of trials, and the subject is asked to name the color in which the word is printed. A control version of the task, in which subjects are required to name the colors of sets of asterisks or zeros, is also administered to each subject. Stroop interference scores (on accuracy and speed) are obtained by subtracting a subject's score on the control stimuli from the subject's Stroop score.

Poststimulation deficits in performance occurred in all five of the studies and on all three of the tasks. Except for a lack of effect on the proofreading task in one study (p. 80), the effects were totally reliable. Moreover, Glass and Singer (1972, p. 47; see also, Glass, Singer, & Friedman, 1969, Experiment 1) reported poststimulation effects following exposure to 56-dB random noise as well as to the more intense 108-dB bursts.

There have been a number of successful attempts at replicating the poststimulation ef-

fects of unpredictable high-intensity noise on human performance. Thus Rotton, Olszewski, Charleton, and Soler (1978) reported less tolerance for frustration among subjects exposed to 80-dB (A) random-intermittent bursts of conglomerate noise than among subjects working in quiet. Likewise, Gardner (1978) found that subjects exposed to random-intermittent bursts of conglomerate noise at 100 dB (A) provided poorer poststimulation performance on a proofreading task than did subjects not exposed to noise. Percival and Loeb (in press, Experiment 1) found less tolerance for frustration among subjects exposed to random-intermittent, 95-dB (A), conglomerate noise than among subjects exposed to a continuous, soft (46-dB) broadband sound. Percival and Loeb did not, however, find poststimulation effects on proofreading performance.

Studies of the impact of variable continuous noise, when there are unpredictable components of the noise (e.g., aperiodic bursts of static or office noise), also report poststimulation effects. Thus Wohlwill, Nasar, DeJoy, and Foruzani (1976) found less tolerance for frustration among subjects exposed to 30 minutes of continuous 80–85-dB (A) conglomerate noise than among subjects working in quiet. Sherrod, Hage, Halpern, and Moore (1977) found similar effects for 18 minutes of continuous exposure to 94-dB (A) conglomerate noise. Finally, Rotton et al. (1978) found that those exposed to 15 minutes of meaningful speech (two lectures on phobias) at 80 dB (A) had less tolerance for frustration following stimulus termination than did a no-speech (quiet) control group.

Attempts by Harris (Note 1) to replicate the poststimulation effects of unpredictable noise were less fruitful. Harris reported three studies, one in which he used noise [85–105 dB (A)] from an automobile horn and two in which he used a conglomerate noise of similar intensity. All three of the studies included both fixed and random-intermittent noise conditions and a quiet control group. Harris failed to find postnoise performance decrements on either proofreading (Experiments 1 and 2) or a serial search task (Ex-

periment 3). It should be noted, however, that the average level of proofreading performance for his subjects was very low in all conditions, which suggests a floor effect.

A failure to replicate the postnoise effect was also reported by Frankenhaeuser and Lundberg (1974). After exposure to 40 minutes of aperiodic bursts of 65-85-dB (A) conglomerate noise, subjects did not show less (or more) tolerance for frustration than after working on a task without noise or after relaxing. The tolerance for frustration score in this study was the time that a subject was willing to spend on an insoluble task after an obligatory period of 80 minutes on that task. It is likely that because of the long period of required work, this measure is considerably less sensitive than the Feather measure, which has no obligatory work period.

Two studies reported by Moran and Loeb (1977) similarly failed to find a noise aftereffect. Participants were exposed to recordings of aircraft overflights [peaking at 90-105 dB (A)] that were either continuous or random-intermittent. A quiet experimental control group was also included. There were no effects of the noise (continuous or random-intermittent) on either the tolerance for frustration or the proofreading task. The authors pointed out, however, that it is possible that neither of the noise conditions in these two studies was actually unpredictable, since aircraft noise peaks were always signaled by onset of the overflight noise. This explanation is supported by later work from Loeb's laboratory (Percival & Loeb, in press, Experiment 2) in which decreased persistence on the tolerance for frustration task was found to occur after exposure to random-intermittent bursts of conglomerate noise and after exposure to random-intermittent bursts of aircraft noise peaks (eliminating the gradual onsets and offsets) but not following exposure to recorded normal aircraft flyovers (which include gradual onsets and offsets). There were no effects of any of the noise exposure manipulations on poststimulation proofreading performance.

DeJoy (Note 2) failed to find poststimulation effects of either random or fixed-intermittent 85-dB (A) print shop noise on either

a proofreading or an insoluble anagrams task. Since the anagrams task was affected by task load during noise (discussed later), it appears that this task was sensitive to a poststimulation effect but that the noise failed to produce the effect.

Although the Glass and Singer (1972) work suggests that poststimulation effects occur only following unpredictable noise, two studies reported similar deficits following exposure to high-intensity, steady-state (no unpredictable components) continuous noise. Thus Hartley (1973) found deterioration of performance on a five-choice reaction time task following a 20-minute exposure to 100-dB (A) continuous broadband noise, as opposed to exposure to the same noise at 70 dB. Broadbent (1979) similarly exposed subjects to a broadband continuous noise of either 55 or 85 dB (C). The interference score on the Stroop Color-Word task was not affected by the sound level of the previous noise exposure. However, after noise, but not after quiet, subjects named patches of colored inks relatively faster than they read color names printed in black. Since both the Broadbent and the Hartley studies were primarily concerned with variations in sound level (there were no no-noise control groups), the effects they reported may depend on variations in intensity rather than on stimulus predictability (cf. Broadbent, 1977). This argument receives inferential support from Broadbent's (1979) failure to find effects of the high-versus low-intensity sound on Stroop interference, which has been reliably affected in those studies that compared an unpredictable noise condition to a quiet control group.

As is apparent from Table 1, nearly all of the studies that used steady-state continuous and variable continuous noise found poststimulation deficits in performance. As mentioned previously, it is possible that the effect of steady-state continuous noise depends on variations in intensity, whereas that of variable continuous noise depends on variations in predictability. As is apparent from Table 2, results of studies of random-intermittent exposure are less consistent. Possible reasons for the failure of a number of these studies to replicate the Glass and Singer

Table 1
Nature of Noise Stimulus and Aftereffect Measures in Studies That Used Continuous Noise

Study	Description of noise	Performance aftereffects measure	Duration of noise	Sound level	Mode of delivery
Broadbent (1979)	Broadband, steady state	Stroop interference	20 min.	85 dB (C)	Speakers
Hartley (1973)	Broadband, steady state	Color naming/reading names of colors ^a Five-choice reaction time ^a	40 min.	100 dB (A)	Speakers
Rotton, Oiszewski, Charleton, & Soler (1978)	Meaningful speech	Tolerance for frustration ^a	15 min.	80 dB (A)	Earphones
Sherrod, Hage, Halpern, & Moore (1977)	Conglomerate (with aperiodic bursts of electronic static)	Tolerance for frustration ^a	18 min.	94 dB (A)	Speakers
Wohlwill, Nasar, DeJoy, & Foruzani (1976)	Conglomerate (with aperiodic bursts of office noise)	Tolerance for frustration ^a	30 min	80-85 dB (A)	Speakers
Moran & Loeb (1977) Experiments 1 and 2	Aircraft sounds	Tolerance for frustration, proofreading	14.34 min.	90-105 dB (A) peaks	Not reported

^a The noise described was associated with a deficit in performance on that aftereffect task.

(1972) work (particularly, Frankenhaeuser & Lundberg, 1974; Moran & Loeb, 1977; Harris, Note 1) have been presented earlier and are noted in Table 2. There appear to be no consistent differences between those intermittent noise studies that found aftereffects and those that failed to find aftereffects on the number of noise bursts, duration of noise exposure, percentage of the total period that they were exposed to noise, sound level, and whether the noise was delivered through ear-phones or speakers.

In sum, the data on poststimulation effects of noise on performance are consistent for variable continuous and steady-state continuous noise and mixed for intermittent exposure. The relative reliability of the poststimulation effect following continuous as opposed to intermittent sound may be attributable to the greater exposure time (noise on) in continuous noise studies. Nevertheless, if we confine ourselves to those studies that used clearly unpredictable noise and reasonably sensitive aftereffects measures, even the intermittent literature provides considerable support for the reliability of the postnoise effect.

Crowding. Those who study the effects of crowding on human behavior have found it useful to distinguish between two kinds of density—social density and spatial density (cf. Loo, 1973). Social density is manipulated by varying the number of people occupying a fixed quantity of space, and spatial density is manipulated by varying the available space but keeping the number of people constant. Since there is evidence that the effects of density are to some degree dependent on this distinction (e.g., Baum & Koman, 1976), the following review of the effects of high levels of density on poststimulation performance will similarly distinguish between these two kinds of density.

In an early study of the aftereffects of spatial density, Sherrod (1974) had groups of eight female high school students perform a number of tasks in either a large or a small room. After 1 hour of exposure, subjects were moved into a large reception area. Each student, at her own desk, was administered the tolerance for frustration and proofreading

tasks. Those subjects who had been working in high density (small room) showed less tolerance for frustration than did their low-density (large room) counterparts. There were no differences on the proofreading task.

Similar postcrowding deficits on the Feather tolerance for frustration task are reported by Evans (1979) with mixed-sex groups of 10 persons and by Nicosia, Hyman, Karlin, Epstein, and Aiello (in press) for both male and female groups with 4 persons. The latter study, however, failed to find any poststimulation effects of high density on a visual search task and a problem-solving task. In a final study, Aiello, DeRisi, Epstein, and Karlin (1977) reported that following 30 minutes of sitting in a room with 3 other subjects, female undergraduates who were crowded (small room) scored lower on two measures of creativity than did their uncrowded (large room) counterparts. In sum, all four of the existing studies of the aftereffects of spatial density reported poststimulation effects.

There are two studies of the poststimulation effects of social density. The first was conducted by Saegert, Mackintosh, and West (1975, Experiment 2) in a railroad station in midtown Manhattan. Male and female subjects were asked to do a number of tasks during a crowded or uncrowded time of day. After task completion, the subject was brought to a quiet secluded place and administered the Stroop Color-Word task. Whereas females who had been exposed to high levels of density performed more poorly on the Stroop than did their low-density counterparts, males performed better after high- than after low-density exposure. Although other studies have found interactions between density and gender on a number of dependent measures (see Sundstrom, 1978, for a review), the relationship between one's gender and whether one experiences stress in a particular high-density setting is still unclear. As a consequence, we do not know whether it is the males or the females who are experiencing stress in this situation, and thus it is impossible to determine whether these data indicate a poststress effect.

In a study by Dooley (1978), groups of

Table 2
Nature of Noise Stimulus and Aftereffect Measures in Studies That Used Random-Intermittent Noise

Study	Description of noise	Performance aftereffects measure	No. of bursts	Duration of noise	Percentage of time on	Sound level	Mode of delivery	Comments
Gardner (1978)	Conglomerate	Proofreading ^a	24	3.6 min.	15	100 dB (A)	Earphones	
Glass & Singer (1972) (pp. 47, 50, 52, 55, 80)	Conglomerate	Tolerance for frustration ^a Proofreading ^{a,b} Stroop ^a	23-25	3.6-5 min.	15-20	55 and 108 dB (A)	Speakers	
Percival & Loeb (in press)								
Experiment 1	Conglomerate	Tolerance for frustration ^a Proofreading	24	3.6 min.	15	95 dB (A)	Speakers	
Experiment 2 ^a	Aircraft overflights Aircraft overflight peaks White noise Conglomerate noise	Tolerance for frustration ^a Proofreading	16	7.13 min.	29	95 dB (A)	Speakers	
Rotton, Olszewski, Charleton, & Soler (1978)	Conglomerate	Tolerance for frustration ^a	60	9 min.	60	80 min.	Earphones	
DeJoy (Note 2)	Printing shop noise	Proofreading frustration	60	10 min.	33	85 dB (A)	Speakers	
Frankenhaeuser & Lundberg (1974)	Conglomerate	Tolerance for frustration	20	40 min.	50	65-85 dB (A)	Speakers	Insensitivity of measure of frustration tolerance
Harris (Note 1)								
Experiment 1	Auto horn	Proofreading	30	3.8 min.	12.5	85-105 dB (A)	Not reported	Possible floor effect
Experiment 2	Conglomerate	Proofreading	30	3.8 min.	12.5	85-105 dB (A)	Not reported	on proofreading in
Experiment 3	Conglomerate	Serial search	30	3.8 min.	12.5	85-105 dB (A)	Not reported	Experiments 1 and 2
Moran & Loeb (1977)	Aircraft overflights	Tolerance for frustration	14	4.6 min.	29	90-105 dB (A)	Not reported	Aircraft noise peaks were always signaled by the onset of overflight noise

^a The noise described was associated with a deficit in performance on that aftereffect task.

^b A proofreading effect was found in all but one study (Glass & Singer, 1972, p. 80).

^c Decreased tolerance for frustration occurred following aircraft overflight peaks and conglomerate noise but not following aircraft overflights and white noise.

either three or nine male undergraduates performed a simulated marketing task in a small room. In an experimental control group, a single subject performed the same task alone. After task completion subjects were moved to individual cubicles in which they were administered a proofreading task. Results indicated that the poststimulation effects in this study were mediated by individual differences in personal space needs. Both high- and low-density conditions (as opposed to the alone condition) had a negative impact on the proofreading quality of subjects with far (need more) personal space but not on those with close (need less) personal space. It appears that the mere presence of others in the small room, rather than the manipulated level of high density, acted as the stressor in this study. Moreover, those subjects who were most likely to experience stress when involved in close interactions with others (i.e., those with far personal space) showed aftereffects. Those less likely to experience stress (i.e., those with close personal space) did not show the effects. In sum, there is evidence for a postdensity effect in cases in which the close presence of others is likely to be experienced as stressing.

Task load. Three studies have indicated that subjects who experience a high task load perform more poorly following task completion than those assigned a low task load. Thus Cohen and Spacapan (1978, Experiment 1) found in a four-choice reaction time experiment that those required to respond to 100 lights per minute had less tolerance for frustration following task completion than those responding to 50 lights per minute. There were, however, no effects of task load on proofreading performance. (This experiment controlled for subjects' perceptions of success-failure and thus is not explicable in those terms.) Hartley (1973) reports that those required to perform a serial reaction time task for the first 20 minutes of the experiment performed more poorly on the same task in the last 20 minutes than those who read during the initial stage of the study. (This effect may, of course, be attributable to boredom on the part of those required to perform the same task twice.) Similarly, Rot-

ton et al. (1978) found that the expectation that one would be required to recall a speech, even though one was never actually required to do so, resulted in lower tolerance for frustration following task completion than for those not expecting a recall test. DeJoy (Note 2), however, found no differences in tolerance for frustration (insoluble anagrams task) or proofreading following performance of a high-versus a low-load coding task.

Other social and nonsocial stressors. Glass and Singer (1972) also reported that poststimulation deficits in performance occur following electric shock, a frustrating experience with a bureaucracy, and an experience of arbitrary or sex discrimination. In the electric shock study (Glass & Singer, 1972, p. 110) those subjects exposed to unpredictable and uncontrollable shock performed more poorly on both the Stroop and proofreading tasks following exposure. A later study (Glass et al., 1973), found similar poststimulation effects of electric shock on the Stroop. Experiences of bureaucratic harassment (Glass & Singer, 1972, p. 124) similarly resulted in poorer proofreading for the harassed than for the nonharassed groups after the experience had ended, and the study of the effects of discrimination in the amount of pay received for participating in the experiment (p. 132) found that those who experienced discrimination performed more poorly on the Stroop following the experience than those who did not experience discrimination.

Conclusions. The previously cited studies provide evidence for both the reliability and generality of the poststimulation effect of stress on performance. These effects have appeared in the vast majority of studies, and these studies have used a wide range of stressors. The data suggest that the effect is most likely to occur when the stressor is clearly unpredictable and when a sensitive aftereffects measure is used. Moreover, factors that might mediate the stressfulness of the situation (e.g., subject gender and need for personal space in the social density studies) are important determinants of whether a particular manipulation will produce an aftereffect. The most reliable mea-

asures appear to be those used by Glass and Singer (1972), although the proofreading task has proved less reliable (e.g., Cohen & Spacapan, 1978; Glass & Singer, 1972, p. 80; Sherrod, 1974) than the Feather and Stroop tasks. The inconsistency of the proofreading measure may be attributable to the large variation among subjects' literary skills that often results in substantial error variance on proofreading scores. Although other measures have only been used in individual studies, poststimulation effects have been obtained on a serial reaction time task (Hartley, 1973) and a creativity task (Aiello et al., 1977). Aftereffects measures that have failed include visual search tasks (Nicosia et al., in press; Harris, Note 1) and a problem-solving task (Nicosia et al., in press). Since in all of the Glass and Singer studies and replications, the poststimulation tasks were administered shortly after stressor termination, there are no data on the time course of the effect.

Predictable Versus Unpredictable Stressors

Glass and Singer reported five studies that compared the poststimulation effects of predictable versus unpredictable noise. The first two studies (Glass et al., 1969, Experiment 1; see also, Glass & Singer, 1972, pp. 47, 52) compared fixed versus random-intermittent exposure to a broadband conglomerate noise made up of a number of fairly typical urban sounds. In both of these studies, those exposed to unpredictable noise performed more poorly than did the predictable noise group on both the tolerance for frustration and proofreading tasks. There was no difference between poststimulation performance of the predictable noise group and a no-noise control group. The first study also indicated that predictability of the noise was a more important determinant of poststimulation effects than was the intensity (56 vs. 108 dB) of the sound. In a third study (Glass & Singer, 1972, p. 55) predictability was manipulated by the use of signaled (by a light) versus unsignaled (light occurrence is random) noise bursts. Again, those exposed to unpredictable noise were less persistent on insoluble puzzles administered after noise

termination. The effect of unpredictable noise on proofreading was, however, not replicated.

Predictability was manipulated in two other studies that were primarily designed to assess the effect of inhibiting adaptation on post-stimulation effects. (See the section on Adaptive-Cost Hypothesis under Theory Review.) The first study was the only one in which Glass and Singer (1972, p. 141) reported a clear reversal of the predictability effect. For subjects working on difficult math problems during exposure, higher frustration tolerance and better proofreading occurred in the random-intermittent condition than in the fixed-intermittent condition. This was not true for those working on simple problems. The second study (Glass & Singer, 1972, p. 147) resulted in the usual predictability effect with those who were exposed to random-intermittent noise, whether the interburst intervals were 51 sec or 96 sec, performing more poorly on the proofreading task than those who were exposed to fixed-intermittent bursts.

Gardner (1978, Study 1, Table 1) similarly presented subjects with fixed or random-intermittent conglomerate noise of 100 dB. A proofreading task performed after noise exposure was performed more poorly by those exposed to unpredictable than by those exposed to predictable noise. Likewise, Percival and Loeb (in press) reported that subjects exposed to 24 minutes of 95-dB random-intermittent conglomerate noise showed less tolerance for frustration following exposure than either those exposed to equivalently intense fixed-intermittent sound or those exposed to a soft (46-dB) broadband sound. Studies by Harris (Note 1), Moran and Loeb (1977), and DeJoy (Note 2) described earlier also manipulated the predictability of the noise. As mentioned earlier, none of these investigations indicated aftereffects of either predictable or unpredictable sound.

In sum, the role of predictability in producing stress aftereffects has not received considerable attention since the publication of the Glass and Singer book. Existing evidence does, however, suggest that aftereffects are more likely to occur following exposure to the unpredictable rather than a predictable stressor.

Controllable Versus Uncontrollable Stressors

Glass and Singer (1972) reported a number of studies which indicated that the after-effects of stress occur following uncontrollable but not controllable stressors. First, there were two identical studies (pp. 64, 65) that used 108-dB aperiodic noise in which half of the subjects were instructed how to terminate the noise by pressing a button (perceived control). In fact, the perceived control subjects did not actually terminate the noise. In both studies, following noise exposure, those provided with perceptions of control over stimulus termination had more tolerance for frustration and performed better on the proofreading task than did their counterparts without perceptions of control.

In a third study, Glass and Singer (1972, p. 69; see also, Glass, Reim, & Singer, 1971) tested the proposition that indirect control (i.e., having access to another person who could terminate the noise) would be similar to having direct control over noise termination. Their hypothesis was confirmed. Following exposure to the 108-dB conglomerate noise, those with indirect control performed better than those lacking the perception that they (or their partner) could control the termination of the noise. In a final study, Glass and Singer (1972, p. 74) found that knowing that someone else was able to terminate the noise (for themselves) during the experiment but that one's own exposure could not be terminated (relative deprivation) did not increase poststimulation effects. However, as in previous studies, a proofreading task administered after stimulus termination was performed more poorly by those lacking perceived control than by those with control.

A replication of the aftereffects of noise that used a slightly different operation of perceived control is reported by Gardner (1978). An inability to replicate Glass and Singer when using an informed consent form that explicitly informed the subject that he or she could leave the experiment without loss of pay led Gardner to use the informed consent form as a way of manipulating control. Gardner reported that although it was impossible to replicate the aftereffects of unpredictable, uncontrollable noise with in-

formed consent, the effect was replicable when informed consent was not required. Unfortunately, those who received the informed consent were not only given the perception of control over termination of the stressor (i.e., they could leave at will) but also were making an explicit choice (to the extent of signing their names) to participate in the study prior to noise exposure. Thus, it is unclear whether the ameliorative effects of informed consent in this study are attributable to increased control or to increased choice and commitment.

Perceived control over the termination of the stressor was also examined in the previously described study of spatial density by Sherrod (1974). Besides the high-density (small room) and low-density (large room) conditions, an additional condition was included in which subjects were assigned to a high-density setting but were told that they could leave the room and work in a larger room if they so desired (density with perceived control). As in the noise studies, the perceived control subjects did not actually use this option. The high-density group showed the least persistence on the insoluble puzzles, followed by an intermediate level of persistence by those high-density subjects with perceived control, and finally, the most persistence was shown by the low-density group. As mentioned earlier, there were no effects on the proofreading task.

The previously described studies all provided subjects with the perceived ability to terminate the stressor, but in all cases subjects did not actually perform any coping responses. That is, they knew they could terminate the stressor but did nothing about it. A slightly different form of control was offered to subjects in a study of the after-effects of electric shock reported by Glass et al. (1973). During an initial trial block, all of the subjects received a series of 10 6-sec shocks and were required to press a reaction time key at the onset of each shock. During a second block of trials, the perceived control group was told that they could decrease the duration of each shock (from 6 to 3 sec) by maintaining a fast reaction time to the onset of the shock. For half of these sub-

jects, all shocks were halved (perceived control with reduction), and for the remaining subjects none of the shocks were halved (perceived control without reduction). Two experimental control groups received shocks of either 3 sec (no perceived control with reduction) or 6 sec (no perceived control without reduction) but were given no indication that shock duration was related to their behavior. Thus in this case, subjects with control were actually implementing that control by attempting to maintain fast reaction time. Performance on the Stroop, administered after the two blocks of shock trials were completed, indicated that subjects who were told that they could control the duration of the shock and ostensibly succeeded in doing so (perceived control with reduction) performed better on the Stroop than both of the no-perceived-control groups and better than the group given the expectancy that control was possible who actually failed to control (perceived control without reduction).

A number of studies of the learned helplessness phenomenon have also examined the effects of implemented control over a stressor on poststress performance. Compared with those with the ability to escape or avoid loud noise, those lacking control subsequently performed more poorly on anagrams (Gatchel, McKinney, & Koebernick, 1977; Hiroto & Seligman, 1975), a concealed figures test (Krantz & Stone, 1978), and a proofreading task (Krantz & Stone, 1978). In contrast to the previously described studies, subjects in the unavoidable, unescapable stress conditions in these studies experienced failure as well as stress. (The unavoidable stress conditions in these studies are similar to the perceived control no-reduction condition in the study by Glass et al., 1973, described previously.) The fact that control and success-failure are confounded in these studies makes it difficult to assess whether the mechanisms involved are the same as in the other aftereffects work (cf. Cohen, Rothbart, & Phillips, 1976; Griffith, 1977).

Two recent studies of helplessness induced by exposure to uncontrollable bursts of noise (tones) provide data that are inconsistent with those reported in the aftereffects litera-

ture (Gatchel, Paulus, & Maples, 1975; Gatchel & Proctor, 1976). Both of these studies included an experimental control group in which subjects were instructed to merely sit and passively listen to loud tones (no success or failure). This condition is similar to an unpredictable, uncontrollable stressor condition in the aftereffects paradigm and thus would be expected to result in poststimulation deficits in performance. Although a learned helplessness group, who thought they could escape the noise but actually could not, showed poststimulation deficits on an anagram task, the group who passively listened to the tones did not show deficits. The noise dose in these experiments, however, was small in comparison with previously cited noise studies.²

The research discussed previously has been limited to studies that provided control over the termination of a stressor. A study of the aftereffects of noise by Sherrod et al. (1977) extended this work by investigating the relative contribution of control over initiation of the stressor as well as over termination. Subjects with initiation control were allowed to choose whether they would be exposed to noise. The experimenter stressed, however, that for the purposes of the study, he would prefer that they turn the noise on (they all did). Subjects without initiation control were given no such choice. Termination control was provided in the same way as in the Glass and Singer studies. Following noise exposure the Feather task was administered. Sherrod and his colleagues reported that the least

² At the beginning of both of these studies, the subject, after hearing a sample tone, was offered the opportunity to withdraw from the experiment. As we outline later in this article, such a choice, by providing a form of control over the situation, is likely to ameliorate any poststimulation effects (cf. Sherrod et al., 1977). If we assume that the learned helplessness effect in these studies was a response to failure and not to a lack of control, it is possible that the ability to choose whether to participate in the study ameliorated control-related effects for the passive listening group but did not affect the learned helplessness (failure) group. Admittedly, however, these studies constitute an additional failure to replicate postnoise effects, and this post hoc explanation must be viewed as only tentative.

tolerance for frustration was shown by those who lacked any kind of control over the noise, intermediate tolerance was shown by those with initiation control, termination control caused an even greater increase in tolerance, and combined control (both initiation and termination) caused the greatest increase. Thus although initiation control was not as effective as termination control, increasing overall perceptions of control by combining initiation and termination was the most effective intervention.

In a field study of the stress involved in donating blood, Mills and Krantz (1979, Experiment 1) investigated the roles of providing information about a threatening event and of providing choices about that event in mediating poststress response. Information and choice were both conceptualized as forms of personal control because they presumably allow one to alter or affect their outcomes. In this study, blood donors were offered or not offered a choice of which arm blood would be drawn from. This manipulation offers some control over the procedure but not directly over either the initiation or termination of the stressor. Also, although all donors received some information prior to the procedure, in half of the cases (high information) this information dealt with the details of the procedure and the sensations the donor might expect, whereas in the remaining cases (low information) the information was limited to a general description of the Red Cross blood donor program. The Stroop Color-Word test was administered during the donor recovery period. There were no differences between conditions in Stroop performance. However, the authors pointed out that the nursing interventions during the procedure and the refreshments given to donors following the procedure precluded an adequate assessment of aftereffects in this setting. In addition, the time that elapsed between the stress experience and the aftereffects measure was long in comparison with previously discussed studies in which the aftereffects measures were administered either immediately or after a short respite.

A laboratory study of cold stress by the same authors (Mills & Krantz, 1979, Ex-

periment 2) similarly manipulated information about the stress experience and choice of hand to be placed in the cold water. In this case, however, those who were allowed to choose the hand to be used could also elect to remove their hand from the cold water if they chose to do so. The proofreading measure was administered following stressor exposure. Subjects with choice of hand and perceived control over stressor termination (high choice) were more accurate proofreaders than those given neither choice nor the perception of control (low choice). Also under low-choice conditions, providing information led to improved performance, whereas under high-choice conditions, providing information made little difference. It appears that in this case combining two forms of control did not further decrease poststress effects. It should be pointed out, however, that the high-choice condition itself involved two forms of control (hand choice and immersion time in cold water). Thus, it might be more accurate to conclude that the addition of a third form of control did not decrease poststress effects.

In a final study, DeJoy (Note 2) compared posttask performance of subjects who had some control over a difficult coding task (self-paced) with the performance of subjects who lacked task control (experimenter paced). The two conditions were yoked (average stimulus exposure time of self-paced subject used for experimenter-paced subject) to equate conditions on time on task. Experimenter-paced subjects performed more poorly on an insoluble anagrams task (tolerance for frustration) administered immediately following completion of the coding task than did self-paced subjects. There were no effects on the proofreading task.

Conclusions. The data are almost unanimous in supporting the role of both perceived and implemented control over termination of a stressor in ameliorating stress aftereffects. In some cases those groups with control performed as if they were not exposed to a stressor (e.g., Gardner, 1978; Glass et al., 1973), whereas in others (e.g., Sherrod et al., 1977) control provided some improvement in poststress task performance but did not com-

pletely ameliorate the effect. The single study of initiation control similarly suggests a lessening in poststress performance deficits. Initiation control does not, however, appear to be as effective as termination control. There is also some mixed evidence that providing subjects with choice over an aspect of the stress situation and/or with information about the procedure and expected sensations similarly lessens the poststimulation impact of the stressor.

Is providing someone with more than one kind of control a more powerful intervention than providing them with a single mode of control? The combination of initiation and termination control does prove to be more effective than either of these modes alone (Sherrod et al., 1977). However, the combination of two kinds of choice and one kind of information control does not seem to be more effective than either of these modes alone (Mills & Krantz, 1979). It could be that combined modes of control do help to reduce poststress performance deficits until one reaches levels equivalent to performance following no-stress conditions (as in the Sherrod et al., 1977, study), but additional control is unimportant if that level is already reached (as in Mills & Krantz, 1979).

The research clearly demonstrates that providing one with increased control over a stressor or over a stress setting decreases deficits in poststimulation performance. None of the reviewed studies, however, have investigated whether increased control over a setting is beneficial when there is no stressor present. (This assumes that the demanding coding task used in the DeJoy, Note 2, study was experienced as a stressor.) That is, since none of these studies included a condition that provided control over a nonstressing setting (e.g., perceived ability to leave if the experiment is not fun or choice of task or task order on a simple task), it is unclear whether there is an interaction between stress and control or a main effect for control. Since there is some evidence that perceived control over a simple task setting may improve performance in that setting (Perlmutter & Monty, 1977), an overall rather than stress-specific effect of control does seem possible.

Aftereffects on Social Behavior

Recent studies on the poststimulation effects of uncontrollable stress on social behavior have extended the scope of the original aftereffects research. For example, two studies have reported decreased poststimulation helping after exposure to unpredictable, uncontrollable stress. In an experiment by Sherrod and Downs (1974), subjects performed a task while listening to either a recording of a soothing simulated seashore or a stressing recording of dixieland jazz plus a male voice reading nonrelevant prose. In a third condition subjects listened to the stressing tape but were told that they could terminate the distracting stimulus if they wished (perceived control). After the completion of the 20-minute experiment, subjects left the laboratory and were confronted by a second experimenter who asked for voluntary help in pretesting some experimental materials. Subjects who listened only to soothing seashore sounds volunteered the most times, followed by subjects who listened to the stressing tape but who had perceived control, followed finally by stress-without-control subjects. Thus, exposure to uncontrollable stress decreased poststimulation helping with the addition of control over the termination of the noise partially ameliorating these effects.

Similar results were found in a study of the aftereffects of density and task load conducted in a large shopping center (Cohen & Spacapan, 1978, Experiment 2). Subjects were required to perform high- or low-information rate shopping tasks during periods in which the shopping center was crowded or uncrowded. After completing their task, subjects (on their way to meet the experimenter) entered a deserted corridor in which they encountered a woman who feigned dropping a contact lens. Those subjects who performed high-load tasks and/or were crowded helped less often and for less time than their low-task-load, uncrowded counterparts.

Increased aggressive behavior following exposure to uncontrollable stress was reported by Donnerstein and Wilson (1976). In their experiment, subjects completed a math task under either quiet, high-intensity noise or

high-intensity noise with perceived control over the termination of the noise. Following noise exposure, half of the subjects were angered (by the person they would later aggress against) and half of the subjects were not angered. Angered (but not nonangered) subjects with no control revealed an increase in aggression, whereas the level of aggression of perceived-control subjects was no different than that of no-noise subjects.

Three studies described earlier also used poststress measures of social behavior. Thus Rotton et al. (1978) found that both loud speech and the combination of conglomerate noise and a taxing task reduced one's ability to differentiate among people occupying different roles. Epstein and Karlin (1975) reported that groups of men who were crowded were less cohesive and more competitive following the stress experience. Women, however, were more cohesive and less competitive following the crowded versus noncrowded experience. Finally, Dooley (1978) failed to find any relationship among social density, volunteering for a future experiment, or rating of attractiveness of same-sex persons.

Overall, it appears that exposure to unpredictable and uncontrollable stress is followed by a decreased sensitivity to others. This includes a decrease in helping, a decrease in the recognition of individual differences, and an increase in aggression.

Naturalistic-Correlational Studies of Aftereffects

A number of recent studies have investigated the impact of living and/or working in a stressful environment on task performance and social behavior outside of the stressing environment. For example, several investigators have examined the effects of prolonged exposure to community noise on the performance of elementary school children. In one study, Cohen, Glass, and Singer (1973) tested children living in apartment buildings built on bridges spanning a busy expressway. When tested in a quiet setting, children who lived in noisier apartments showed greater impairment of auditory discrimination and reading ability than did those who lived in quieter apartments. The length of residence increased

the magnitude of the correlation between noise and auditory discrimination. Additional analyses ruled out social class variables and hearing losses as possible explanations. A study of children attending school in the air corridor of a busy metropolitan airport (Cohen, Evans, Krantz, & Stokols, 1980) indicated that children living and attending school in the air corridor were poorer on both a simple and a difficult puzzle-solving task and were more likely to give up on the task than their quiet neighborhood counterparts. Again, there were controls for social class and for hearing damage. Unlike the apartment noise study, this study did not find that children from noisy environments (schools) had poorer verbal abilities.

A study of 4½- to 6½-year-old children from homes described by their parents as either noisy or quiet similarly suggests poorer post-stimulation task performance on the part of children from noisier homes (Heft, 1979). The children performed a simple matching (visual search) task and then were administered a recall test for some of the incidental stimuli in that task. Children from noisy homes performed more poorly on both the matching and incidental memory tasks than those from quieter homes. Performance on a second matching task indicated similar deficits for children from noisy as opposed to quiet homes. Analyses controlled for age, preschool experience, and income level of parents. It should be noted, however, that self-reports of noise level do not usually correlate highly with objective noise measures (cf. Kryter, 1970) and thus limit the generality of these findings.

Two naturalistic investigations of crowding also suggest effects that occur outside of the stressing environment. Baum and Valins (1977) reported a number of studies of the behavior of dormitory residents who, because of dormitory design, were exposed to prolonged and repeated personal encounters with large numbers of other residents (long-corridor residents) versus those whose forced encounters included a comparatively small number of others (short-corridor and suite residents). Under controlled conditions outside of the dormitory, those who had a large

number of personal encounters showed less group consensus after a discussion, sat further away from, spent less time looking at, and initiated fewer conversations with a stranger (confederate), used a withdrawal strategy more often in a prisoner's dilemma game, and were less likely to assert themselves by asking questions in an ambiguous situation.

Two studies reported by Rodin (1976) similarly suggest aftereffects of residential density. In the first study 6-9-year-old children from high-density apartments of a low-income housing project were less likely than children from less dense homes from the same project to control (choose) their own outcomes. In a second study, eighth-grade children from high-density apartments were more adversely affected by a learned helplessness pretreatment—insoluble puzzles—than were their low-density counterparts. These effects persisted even after statistical control for social class and race were used.

The studies discussed previously suggest that prolonged exposure to a stressor is associated with a number of poststimulation effects on performance and social behavior. Although it is likely that some of these effects are specific to the stressor (e.g., the tendency of those who are forced into constant contact with others to avoid strangers in the Baum and Valins work), a number of the studies indicate a more general helplessnesslike effect (Baum & Valins, 1977; Cohen et al., 1980; Rodin, 1976). It is important to emphasize that these studies are all correlational and thus do not allow causal inference.

The Meaning of the Stressor and the Meaning of the Control Manipulation

Although the data on the effects of uncontrollable stressors on poststimulation performance and social behavior is reasonably consistent, there have been a number of published and unpublished² failures to replicate these effects. These inconsistencies are probably inevitable given the complexity of the situation being presented to a subject. First, it is likely that our responses to loud noise and to other potentially stressing stimuli are

mediated by cognitions other than control, and we may often unintentionally invoke such cognitions in our laboratories. For example, Cohen (in press) has outlined a number of situational characteristics of laboratory settings that may affect the meaning of the potential stressor for the subject and consequently, whether it will produce stress-related responses. Among others, these factors include (a) whether the participants in the study are aware that the exposure to the aversive stimulus will last for only a short period (cf. Altman, 1975), (b) the salience of the implied contract between the experimenter and the subject that suggests no harm will come to the subject during the experimental procedure, (c) whether the subject chose to participate in the study and whether an informed consent slip was signed.

Averill (1973) has pointed out that the stress-reducing properties of a personal control intervention similarly depend on the meaning of the control response for the individual. Thus telling a subject that pressing a button will terminate a loud noise may or may not suggest that he or she has control over the termination of the stressor. One alternative interpretation of this intervention might be that the stressor must be pretty dangerous if the experimenter needs to provide an escape mechanism.

Theory Review

Adaptive-Cost Hypothesis

Glass and Singer's (1972) working hypothesis was that the process of adaptation requires cognitive work. This work included searching for appropriate coping responses and/or attempting to redefine the stimulus. Moreover, they assumed that the work required to adapt to unpredictable and uncontrollable stressors was substantially greater than that required to adapt to predictable and controllable stimulation. According to Glass and Singer, the adaptive-cost hypothesis predicts that poorer performance on aftereffects tasks should vary directly with degree

² Unpublished research conducted in my own laboratory. (See, also, Baddeley, Note 3; Evans, Note 4; Stokols, Note 5.)

of adaptation, since a greater degree of adaptation implies a greater amount of adaptive effort. Presumably, increased adaptive effort would deplete one's available psychic energies and would thus result in deficits on subsequent demanding tasks.

Glass and Singer (1972) presented two arguments that led them to discard this hypothesis. First, they assumed that decrements in galvanic skin response (GSR) to noise and shock are valid indices of the cognitive effort involved in adaptation. This follows from their assumption that the greater the adaptation, the greater the amount of adaptive effort. There were no significant correlations between aftereffects scores and indices of GSR adaptation for subjects in various conditions. Thus there was no evidence for differential cognitive work. Second, they assumed that a situation in which one was exposed to unpredictable stress but in which adaptation was inhibited would not result in poststimulation effects. This should be true, since a lack of adaptation implies a lesser degree of adaptive effort. They were successful in inhibiting physiological adaptation in two studies (pp. 141-153) but found poststimulation effects even in the conditions in which subjects did not physiologically adapt. They thus concluded that "it is not the adaptive process that causes adverse aftereffects" (p. 153).

Although the authors describe the effort of adaptation as a cognitive process of searching for appropriate coping strategies and of redefining the stimulus, they take physiological evidence based on one index of autonomic response as the measure of adaptation. Existing knowledge concerning the relationship between cognition under stress and corresponding physiological fluctuations is equivocal at best (cf. Kahneman, 1973). Moreover, it is likely that those subjects who were prevented from physiologically adapting worked just as hard (if not harder) to cope with and redefine the stressor. In other words, it is possible that a significant amount of effort may be expended even if adaptation does not occur. Thus, aftereffects may occur because of the adaptive process even when adaptation fails. In sum, although the Glass

and Singer (1972) data do not provide support for the adaptive-cost hypothesis, neither do they provide convincing evidence to justify its rejection. Unfortunately, none of the more recent studies have attempted direct tests of this explanation.

Information Overload

An alternative form of a psychic cost hypothesis was recently proposed by Cohen (1978). He argued that unpredictable, uncontrollable stressors, because they are potentially threatening, substantially increase demands on attentional capacity. This increased demand might occur because individuals are required to continually monitor potentially threatening stimuli to evaluate their adaptive significance and to decide on appropriate coping responses (cf. Lazarus, 1966). Increased demand may also occur because of effort required in tuning out or inhibiting response to the distracting stimulus. Cohen further suggested that an individual's attentional capacity is not fixed but shrinks when there are prolonged demands. This shrinkage or *cognitive fatigue* presumably increases with both the attentional load of an activity and the duration of an activity. Thus prolonged exposure to an environmental stressor and/or to a high information rate task should result in cognitive fatigue—an insufficient reserve of attention to perform demanding tasks.

What are the implications of the cognitive fatigue hypothesis for the performance of ongoing and subsequent tasks? Task duration under experimental conditions is usually limited to between 20 minutes and an hour. Although this may be sufficient to cause a significant decay in available capacity, it may not affect performance on an ongoing task that by that point is well practiced and requires little effort. Subsequent tasks, however, that demand considerable attention on the part of the subject would be sensitive to fluctuations in available processing capacity. Thus we would expect depletions in attentional capacity resulting from prolonged task and environmental demand to be manifest in deficits on difficult tasks administered immediately after termination of the principal task.

Three recent studies (mentioned earlier) have provided direct support for the cognitive fatigue hypothesis. All three suggested that those experiencing a high task load perform more poorly on subsequent tasks than those experiencing lower task loads. For example, Hartley (1973) reported that both increased task load and increased noise result in poorer performance on a subsequent serial reaction time task performed in quiet. Moreover, there is an additive effect of task load and noise on poststimulation performance. Rotton et al. (1978) similarly reported that deficits on the Feather tolerance for frustration task increase with both task load of a previous task and the addition of noise to that task. Again, there is an additive effect when these conditions are combined. In a final study, Cohen and Spacapan (1978, Experiment 1) reported that deficits on the tolerance for frustration task (but not on the proofreading task) increased as task demand and task duration of a previously performed task increased. Moreover, self-reports of mental fatigue similarly increased with both task load and task duration. Thus subjects' self-perceptions were consistent with both the predictions of the cognitive fatigue hypothesis and the data from the tolerance for frustration task.

A study reported by Wohlwill et al. (1976) is not, however, consistent with the cognitive fatigue hypothesis. They reported that subjects who listened to noise but did not perform a concurrent task showed the same aftereffects as those who worked on a task while listening to noise. Since performing a task under noise should demand greater attentional capacity than merely being exposed to the noise, the cognitive fatigue hypothesis would suggest that the noise plus task condition would show a greater magnitude of aftereffects. Interpretation of this study is difficult, however, since the no-task subjects were given instructions that may have led them to assume that they were expected to process (possibly remember) task stimuli. Unfortunately, the investigators did not administer any self-report measures of cognitive fatigue or ask subjects how they perceived the experimental situation.

Cohen also suggested that posttask (or poststress) attentional deficits can have detrimental effects on interpersonal behavior. He argued that lacking adequate attention reserves, an individual sets priorities for use of his or her attention. The most common strategy is to focus available attention on inputs most relevant to one's own goals, neglecting other cues, social and nonsocial alike (cf. Milgram, 1970). Important social cues that are often neglected when attention is restricted include those that carry information concerning the moods and subtly expressed needs of others. The neglect of such cues results in a lowered probability of helping another, expressing sympathy for another, or reacting appropriately to another's needs. Other proposed social consequences of attentional focusing following high attentional demand include oversimplification and distortion in the perception and evaluation of communications and persons.

Evidence for the contention that conditions leading to cognitive fatigue will result in less sensitivity to others comes from a number of recent studies. In a study conducted in a field setting (Cohen & Spacapan, 1978, Experiment 2), after performing a high-load shopping task, subjects were less likely to help a woman search for a contact lens than their counterparts who performed a low-load task. Similarly, subjects who had been crowded were less likely to help than those who had not been crowded. Again, there is an additive effect in the high task load, high-density condition. Rotton et al. (1978) reported increased difficulty in differentiating between people who occupy different roles following both increased task load and noise exposure. Thus it appears that poststimulation task deficits and insensitivity to social cues can be induced by manipulation of task load as well as by unpredictable stress. Previously cited studies on poststress aggression (Donnerstein & Wilson, 1976) and poststress helping (Sherrod & Downs, 1974) can be similarly viewed from this perspective.

Learned Helplessness Theory

Glass and Singer (1972; see, also, Seligman, 1975) suggested that aftereffect deficits

are attributable to learned helplessness. They argued that subjects who are unable to predict and control a stressor learn that their reinforcements are independent of their responses, which results in motivational decrements that are manifested in poorer performance on poststimulation tasks. Such an interpretation requires at least two assumptions: (a) Learned helplessness can be induced when performance on the experimental task (task performed during stressor exposure) is not instrumental in escaping or avoiding the aversive stimulus; and (b) helplessness will generalize to a wide range of cognitive tasks, including tasks that do not require a direct problem-solving strategy. (Test tasks used in learned helplessness studies usually require subjects to initiate responses in a trial-and-error fashion; cf. Wortman & Brehm, 1975.)

Evidence relevant to this last assumption has been reported by Cohen et al. (1976). These authors found that task impairment on the Glass and Singer aftereffects tasks can be replicated when a more standard learned helplessness pretreatment is used. Employing a pretreatment used by Roth and her colleagues (e.g., Roth & Bootzin, 1974) in previous studies, Cohen et al. found that subjects who received noncontingent reinforcement showed deficits on the tolerance for frustration and the Stroop color word task similar to the deficits found by Glass and Singer for subjects exposed to uncontrollable noise. Further support for the helplessness explanation is provided by a study by Glass and Singer (1972) in which subjects who were told that solving experimental puzzles would terminate the noise, but who actually received insoluble puzzles, took more time to solve a final puzzle that was soluble than those subjects who had been working on soluble puzzles and perceived that they were shortening noise exposure (p. 89). Both of these studies confounded controllability and success-failure. (Cohen et al. did attempt to minimize this effect by yoking the contingent and noncontingent groups on number of reinforcements and number of trials.) As mentioned earlier, a number of learned helplessness studies involved the administration of

escapable or unescapable noise. However, since controllability and success-failure are also confounded in these studies, it is unclear whether they are appropriate analogs of the aftereffects paradigm.

The strongest source of support for the learned helplessness interpretation comes from the naturalistic studies of stress aftereffects. Work in crowded college dormitories (Baum & Valins, 1977), in high-density low-income housing (Rodin, 1976), and in schools located in the air corridor of a busy urban airport (Cohen et al., 1980) all suggested that those living under environmental stress show behavioral manifestations of helplessness.

Although the above data lend support to the helplessness hypothesis, there are recent data that call the helplessness interpretation into question. Seligman (1975) argued that a major consequence of experience with uncontrollable events is motivational—undermining the motivation to initiate voluntary responses that control other events. One manifestation of the motivational deficit is that “helplessness retards the initiation of aggressive as well as defensive responses” (Seligman, 1975, p. 33). A study by Donnerstein and Wilson (1976), however, indicated that after stimulation is terminated subjects who lack control over noise are more (not less) likely than subjects with perceived control over the noise to shock a person who angers them.

The helplessness interpretation is especially compelling because it provides an obvious explanation for poststimulation effects on the extremely reliable Feather task. That is, less persistence on a difficult task is characteristic of helplessness. It is, however, difficult to explain why increased task load would lead to helplessness, especially when success feedback is held constant across conditions (Cohen & Spacapan, 1978, Experiment 1). Moreover, helplessness is accompanied by a relatively negative affective state (Gatchel et al., 1975; Miller & Seligman, 1975; Pittman & Pittman, 1979; Seligman, 1975). Yet aftereffect studies generally reported no differences between conditions in reported affect following stressor exposure (e.g., Cohen & Spacapan, 1978;

Glass & Singer, 1972; Mills & Krantz, 1979, Experiment 2; Pennebaker, Burnam, Schaeffer, & Harper, 1977; Wohlwill et al., 1976). In addition, the overall mood tone of subjects in all conditions is sometimes positive (e.g., Coben & Spacapan, 1978; Wohlwill et al., 1976).

Arousal Theory

A number of investigators have mentioned the possible role of arousal in producing after-effects (e.g., Evans, 1978; Glass & Singer, 1972; Poulton, 1978). The most popular form of this theory assumes that those exposed to uncontrollable and unpredictable stressors show higher levels of arousal immediately following exposure than those exposed to predictable and/or controllable stressors. How would increased arousal affect poststimulation task performance and social behavior? It is generally believed that there is an optimal level of arousal for performance of a particular task (cf. Poulton, 1970). Performance increases with increments in arousal up to that optimal point and decreases as the arousal level increases above that point (the classic inverted U curve). This proposed relationship between arousal and task performance is often attributed to a narrowing of attention that occurs under conditions designed to induce arousal (Easterbrook, 1959). The first inputs to be reduced (dropped out) are those that are irrelevant or only partially relevant to task performance. As arousal increases, attention is further restricted and task relevant cues are also neglected. In some tasks, proficiency demands the use of a wide range of cues (e.g., dual-task performance or single tasks that require the integration of information from many sources). Any narrowing of attention is likely to adversely affect performance of such tasks because remaining attention would likely be less than that required to process task-relevant cues. In other tasks, proficiency demands the use of only a restricted range of cues. Such tasks improve with moderate reductions in attentional span (improvement in performance occurs only to the extent that reducing competing cues facilitates a particular task) but are detrimentally affected

when available attention falls below that required to process task-relevant cues. Thus, continued reduction in attentional span will improve and then impair performance.

It follows that the optimal level of arousal (and thus attentional focus) varies with the complexity (number of cues required) of the task. Optimal levels of arousal for complex tasks are lower than those for simple tasks. Thus high levels of arousal, like those that are presumably elicited by laboratory stress manipulations, are usually assumed to have detrimental effects on complex tasks but not on simple tasks. Assuming that the standard aftereffects measures are complex tasks and that subjects are experiencing a high level of arousal following stressor termination, arousal theory would account for poststimulation deficits in task performance. However, it is unclear whether the standard aftereffects tasks can be considered complex and/or whether they generally show performance deterioration under heightened levels of arousal. For example, existing data show that Stroop performance often improves under arousal-inducing conditions. (See the review in Broadbent, 1971.) This improvement is attributed to an arousal-elicited focusing of attention on appropriate task cues (colors) and to a consequent dropping out of competing cues (words). As an aftereffects task, Stroop performance suffered following exposure to unpredictable and uncontrollable stress. Moreover, the proofreading task could be classified as a simple rather than a complex task, since it involves processing of only a restricted range of cues (cf. Easterbrook, 1959). Thus we might also expect improved performance on proofreading under heightened arousal.

To further confuse the situation, Poulton (1978) has argued that postnoise effects on task performance are due to the level of arousal falling below normal following exposure. If we assume that the standard aftereffects tasks are simple, this approach would similarly provide an explanation for poststimulation effects, since optimal levels of arousal for simple tasks are presumed to be high and any decrease in arousal would cause a decrease in performance.

Insensitivity to social cues can also be ex-

plained by the arousal model if we assume that levels of arousal are increased following exposure to unpredictable, uncontrollable stress. Increases in arousal level are said to be associated with a focusing of attention on cues most relevant to task performance (Easterbrook, 1959; Kahneman, 1973). As suggested in our earlier discussion of Cohen's (1978) attentional model, attentional focusing could lead to an insensitivity to others' needs.

The omnipresent problem in making arousal theory interpretations is the elusiveness of the arousal concept. Although a detailed description of this problem is beyond the scope of this article, it is important to point out that it is unclear how an investigator is to determine a subject's level of arousal. Some argue for behavioral (subjects behave "as they should" when aroused) and self-report measures (cf. Poulton, 1970), and many investigators use physiological measures—usually measures of autonomic response. Unfortunately, behavioral, physiological and self-report measures of arousal do not consistently correlate with one another (cf. Poulton, 1970). Moreover, it is generally accepted that there is no unitary form of physiological arousal (cf. Lacey, 1967) and that individual physiological measures do not correlate with one another. (See the review by Sternbach, 1966.) Nevertheless, many investigations of arousal under stress in laboratory situations use only one or two measures and assume that they reflect a general level of arousal. Thus the first point to be made is that the existing data on the relationship between poststress arousal level and performance are suspect, since we are not sure what arousal is or how it is to be measured and since we are sure that the way it has been measured in the past is inadequate.

Do those exposed to unpredictable and uncontrollable stressors show different levels of physiological arousal than those exposed to predictable and/or controllable stressors after the stressor is removed? There are little existing data on physiological response after exposure is terminated, but there are considerable data on relative levels of arousal at or near the end of the stress session.³ Glass

and Singer (1972) used three phasic measures of arousal in their research: Palmar skin resistance, vasoconstriction of blood vessels in the fingertip, and an electromyographic (muscle tension) measure. They reported that subjects habituate on all three autonomic channels, irrespective of the unpredictability and perceived controllability of the noise. That is, by the end of the exposure period, there is no difference among experimental groups in the levels of reaction to stressor stimuli obtained. A similar lack of differences between conditions in phasic response was reported in two studies of perceived control over the termination of noise by Pennebaker et al. (1977). This lack of differences, however, is inconsistent with some earlier research which suggested that there are significant reductions in electrodermal response, in conditions in which the subject can control or predict the onset and/or offset of stressor stimuli (e.g., Champion, 1950; Corah & Boffa, 1970; Geer, Davison, & Gatchel, 1970).

It is, however, more generally acceptable to use tonic rather than phasic response as a measure of a general level of arousal (cf. Glass & Singer, 1972). The only study that compared tonic response after exposure to predictable or unpredictable noise (Weidner & Matthews, 1978) found that subjects exposed to noise as compared with quiet had

³ The exception to this is evidence that during the initial stage of an anagram test, administered after noise exposure, students exposed to inescapable noise (learned helplessness condition) had a lower skin conductance level (SCL) than did those exposed to escapable noise (Gatchel & Proctor, 1976; Gatchel et al., 1977). An experimental control group in which subjects merely listened to loud tones (equivalent to the Glass and Singer no-control condition) showed the lowest SCL. There were, however, no differences between conditions on skin conductance response in either study. Moreover, the earlier study (Gatchel & Proctor, 1976) found no differences among escape, experimental control, and no-escape (helplessness) conditions following noise for either spontaneous skin conductance fluctuations or heart rate. As suggested earlier, these studies did not find postnoise behavioral aftereffects in the experimental control condition that was similar to the no-perceived-control condition in the Glass and Singer studies.

elevated hand temperature and blood pressure but that subjects exposed to predictable versus unpredictable noise showed no difference. Glass and Singer also reported that there were no differences between various experimental conditions in their studies in the level of skin conductance during stressor exposure, and a later study of control over electric shock (Glass et al., 1973) similarly indicated no difference between conditions in tonic conductance. Some earlier studies, however, suggested that those with control over termination of a stressor do show lower tonic levels during stressor exposure (e.g., Geer et al., 1970), although the evidence is mixed (e.g., Glass et al., 1973; see, also, review by Averill, 1973).

Comparisons of tonic arousal levels under stress and no-stress conditions (no manipulations of control or predictability) have, however, suggested differences at or near the end of the stress session (e.g., Aiello, Epstein, & Karlin, 1975; Evans, 1979), but only mixed support for differences comes from the studies that assessed arousal after the stressor was removed (Frankenhaeuser & Lundberg, 1974; Rotton et al., 1978; Weidner & Matthews, 1978). Thus it appears that there is little evidence for differential levels of physiological response following stressor termination. However, as we have suggested, "the fact that one autonomic measure fails to reveal expected differences does not necessarily rule out the existence of arousal differences" (Glass & Singer, 1972, p. 146).

Self-report measures of stress also provide only meager evidence for differential levels of arousal among the various experimental conditions. Although Glass and Singer (1972) reported a study in which one self-report measure suggested greater stress for those in the unpredictable, uncontrollable stress conditions, as opposed to those exposed to predictable and/or controllable stress (p. 66), for the most part these measures covary with the presence or absence of the stressor but not with the presence or absence of control or predictability. Several later studies (Mills & Krantz, 1979, Experiment 2; Pennebaker et al., 1977) similarly reported no differences between those with and those without control

on self-reports of frustration, tension, and alertness. The previously described study by Sherrod and his colleagues (1977) also found that neither initiation nor termination control affected self-reports of stressfulness.

In sum, there is little evidence for differential levels of arousal following an unpredictable, uncontrollable stressor, as opposed to predictable and/or controllable stressor. Moreover, it is also unclear whether such differences in arousal level would have consistently negative effects on the standard aftereffects tasks.

Frustration-Mood Hypothesis

A simple explanation for the aftereffects of stress is that exposure to unpredictable, uncontrollable stressors causes frustration, annoyance, and irritation, which results in a less motivated performance on poststress tasks and in a lower likelihood of being sensitive to the needs of others. There is evidence that those who experience a negative mood state are less likely to help another (cf. Isen, 1970; Moore, Underwood, & Rosenhan, 1973) and that frustration often results in aggression and other negative interpersonal behaviors (e.g., Berkowitz, 1969). Evidence that those exposed to unpredictable, uncontrollable stressors experience negative mood states following stress termination is, however, equivocal.

The study that comes closest to testing the frustration-mood hypothesis is Donnerstein and Wilson's (1976) investigation of poststress aggression. Consistent with the frustration-mood hypothesis, those subjects who were exposed to noise without perceived control (and thus who were presumably frustrated) and who were also angered (additional frustration) administered more shock to a confederate than either subjects with perceived control over the termination of the noise or those who were not angered. A number of other studies, however, do not indicate any differences in poststress annoyance and irritation between those with and those without perceived control (Glass & Singer, 1972; Pennebaker et al., 1977; Sherrod et al., 1977). Moreover, even studies that compared unpredictable, uncontrollable stressors to no-

stress experimental control conditions often indicated that there were no reliable differences in reported mood between conditions (e.g., Cohen & Spacapan, 1978; Frankenhaeuser & Lundberg, 1974; Wohlwill et al., 1976) and that the overall mood of subjects in all conditions was positive following the experimental session (e.g., Cohen & Spacapan, 1978; Wohlwill et al., 1976). These studies, however, typically include only one or two global items about the "stressfulness" or "enjoyableness" of the experiment and thus may not provide a sensitive measure of mood. As summarized earlier (in the section on Arousal Theory), there is also little evidence for the differential levels of arousal that one might expect to be correlated with increased frustration and mood shifts. In sum, although a frustration-mood hypothesis is compelling because of its simplicity, there are few data which suggest that significant differences in mood or arousal actually exist following the various experimental conditions.

Persistent Coping Strategies

It is possible that those exposed to unpredictable, uncontrollable stressors use coping strategies during stressor exposure and maintain these strategies even after the stressor is terminated. Although a particular strategy may be adjustive during exposure, it may or may not prove to be adaptive after exposure termination. This persistence may be due to overlearning of a coping response (cf. Rodin & Baum, 1978). This approach suggests that the coping response is under stimulus control but is not voluntary. For example, one may cope with crowding by withdrawing and persist in withdrawing from strangers even when not crowded.

The laboratory study of spatial density by Epstein and Karlin (1975) provided evidence for the persistence of a coping strategy that is used during stress exposure. They reported that single-sex groups of women and men differed in their reaction to crowding stress. Consistent with cultural norms, women tended to share their distress with each other, whereas men tended to hide their distress. These norms of sharing and hiding persisted into the poststress session in which men who

had been crowded were less cohesive and more competitive than uncrowded men and in which women who had been crowded were more cohesive and less competitive than uncrowded women. Baum and Valins (1977) studies of dormitory design similarly suggested the persistence of a coping response. Those subjects from dormitories with a high level of forced interaction made more active attempts to avoid the possibility of contact with a stranger outside of the dormitory than those from dormitories with lower levels of interaction. Thus, an avoidance response that presumably developed as an attempt to cope with dormitory life seemed to persist even outside of the dormitory setting.

A persistent coping strategy as a response to prolonged exposure to noise was proposed by Deutsch (1964). She suggested that children reared in a noisy environment eventually become inattentive to acoustic cues; that is, they learn to "tune out" sound. In tuning out his or her noisy environment, a child is not likely to distinguish between speech-relevant and speech-irrelevant sounds. Thus he or she will lack experience with appropriate speech cues and will generally show an inability to recognize relevant sounds and their referents. The inability to discriminate sound is presumed to account, in part, for subsequent problems in learning to read. A child who cannot readily discriminate basic speech sounds faces a difficult task in learning to associate these sounds with their appropriate signs.

A study described earlier by Cohen et al. (1973) found some evidence for this hypothesis by establishing that children who spent their earlier years living in an intensely noisy environment were unable to develop adequate auditory discrimination ability and unable to acquire basic reading skills. There was, however, no direct measure in this study of the tuning out strategy. One strong alternative hypothesis is that the traffic noise made it difficult for the children to hear their parents (speech was masked) and consequently to learn auditory discriminations. A later study by Heft (1979), however, does provide evidence for the use of a tuning out strategy on the part of children living in

noisy environments. If children exposed to noise tune out their acoustic environment, they should be less affected by an auditory distractor than are children from quieter environments. Heft found that the performance of children from homes described by parents as noisy was less strongly affected by the presence of an auditory distractor than was the performance of those from homes described as quiet. Unfortunately, children from noisy homes performed more poorly under quiet conditions than those from quiet homes, which suggests that the lack of a distraction effect might be attributable to a base performance level that could not get much worse under any condition (floor effect).

In sum, evidence from laboratory and naturalistic research suggests that persistent coping strategies are responsible for at least some poststimulation effects. Although the data previously described are limited to situations in which the coping strategy is one that develops as a response to a particular stressor (e.g., withdrawal as a response to crowding), it is possible that general strategies that are used to cope with a wide range of stressors persist after stressor termination (cf. Milgram, 1970). For example, the strategy of focusing one's attention on the essential aspects of a task during exposure (e.g., Hockey, 1970; Wachtel, 1968) may persist even after exposure is terminated. This could account for the decrements in performance on complex tasks reported in the aftereffects literature.

Dissonance and Self-Perception

In their early effort to explain aftereffects, Glass and Singer (1972) alluded to cognitive dissonance (Festinger, 1957) and self-perception analyses (Bem, 1967). Briefly, these analyses suggest that since subjects with perceived control choose to be exposed to the noise for little incentive, they judge it less stressing and therefore do not show aftereffects. However, when Glass and Singer (1972, p. 106) turned to a classical dissonance manipulation—allowing or not allowing subjects to choose whether they would be exposed to noise—they were unable to produce aftereffects on the proofreading or

Stroop tasks. Sherrod et al. (1977), however, reported that allowing subjects to choose whether they would be exposed to noise did partially ameliorate poststimulation deficits in performance. On the other hand, although the choice manipulation in the Glass and Singer study affected a subject's willingness to participate in a future experiment, Sherrod et al. reported that willingness to participate in a future study was unaffected by manipulations of initiation and termination control. Thus the evidence relevant to this hypothesis is at best mixed.

Although these theories provide an explanation for the ameliorative effects of control, they do not explain why poststimulation effects occur in the unpredictable, uncontrollable stressor conditions. Moreover, it is difficult to apply this interpretation to studies in which subjects have control over an aspect of the situation but not directly over the stressor (e.g., choice of hand to be immersed in cold water, Mills & Krantz, 1979) and studies in which the subject actively copes or implements control (e.g., Glass et al., 1973).

Artifacts of the Experimental Situation

Most of the laboratory aftereffects research has been done with both the exposure task and aftereffects tasks conducted in the same laboratory setting and with the same experimenter. One likely explanation for these effects is that subjects exposed to the more aversive stress—that which is unpredictable and uncontrollable—develop a negative attitude about both the experimenter and the experimental setting. Once deciding that he or she does not like either the experimenter or experiments in general, a subject does not work as hard on subsequent tasks. Glass and Singer (1972) attempted to determine the subjects' attitudes about the experimenter by having them fill out an evaluation form following the experimental session. The form was presented in a way that guaranteed the subjects anonymity and suggested that negative evaluations would not be held against the experimenter. Although there were large mean differences (subjects with perceived control liked the experimenter more than

those without control), these differences did not reach statistical significance. Sherrod et al. (1977) also reported no differences between those with and those without control in either liking the experimenter or enjoying the experiment. Later studies that both separated the aftereffects task from the stress situation (e.g., Cohen & Spacapan, 1978; Sherrod & Downs, 1974) and assessed the effects of a naturalistically occurring stressor (e.g., Baum & Valins, 1977; Cohen et al., 1980; Rodin, 1976) are not subject to the artifactual explanation.

Discussion

What Do We Know?

The following is a list of the most striking contributions from the studies reviewed in this article:

1. The poststimulation effects of unpredictable, uncontrollable stress on performance have been replicated in a myriad of different laboratories and with a variety of subject populations. They occur as a consequence of a wide range of stressors including noise, electric shock, density, and cold pressor. Moreover, interventions that increase control and/or predictability are effective in reducing these effects. The bulk of the laboratory work, however, has used a limited number of aftereffects tasks whose common characteristics are not clear.
2. The aftereffects of stress can also be induced by high attentional demands. Thus these effects are not limited to a restricted range of stressful situations that involve a lack of predictability and control over a distracting and/or intense stimulus.
3. There are poststimulation effects on social behavior as well as on performance. These effects generally involve an insensitivity toward others following stress exposure.
4. Poststimulation effects of environmental stressors occur following prolonged exposure in naturalistic settings. These studies generally suggest that these effects are mediated by helplessness. It is, however, unclear whether the mechanisms involved in producing these effects are the same as those responsible for deficits in task performance and in interpersonal response following short-term exposure.
5. There is increasing evidence that various forms of control have ameliorative effects similar to those of perceived control over the termination of the stressor. These include termination control in which one actually performs a coping response (implemented control) as well as initiation, choice, and information control. Moreover, some evidence suggests that combining more than one mode of control will further improve poststimulation performance. This improvement, however, seems to reach asymptote at the performance level reached by the no-stress control condition.

We have documented a wide range of stress aftereffects. Although it would be parsimonious to suggest that after further investigation of the problem, the mechanism responsible for these effects will be isolated, the assumption of a unitary explanation for such a wide range of behaviors may be unreasonable. It is likely that the reliability and generality of poststimulation effects occurs in part because of a multiplicity of causes. Thus the eventual goal of research in this area should be to determine the specific conditions that elicit each of a number of cognitive or motivational mechanisms and to determine specific kinds of tasks and behaviors affected by each.

The research reviewed in this article does not provide evidence from which to accept or reject the adaptive-cost hypothesis from which this literature was spawned. However, many of the proposed explanations for stressor aftereffects are, in fact, forms of that hypothesis. They suggest that poststimulation effects are either directly or indirectly caused by the process of coping with stress. The mechanisms proposed included cognitive fatigue that results from the coping effort, feelings of helplessness that result from a failure to cope, and the overlearning of a coping response. Thus 10 years of intensive research has led to the recognition of the costs of adapting to stress, and although this work has answered few specific theoretical questions, it has provided us with an appreciation of the impact of the adaptive process.

Environmental Stress and Health

Gary W. Evans
Cornell University

Although environmental conditions play a prominent role in health and psychological processes, antecedent factors in these processes have largely been neglected within health psychology. Instead, the focus has been on various markers of health, with considerable attention to stress-related mechanisms, interceding between the environment and health. Another focus within health psychology that has directed attention away from environmental factors has been coping resources, with the examination of either social support, personality, or coping strategies that potentially alter the impact of environmental demands on health. But what characteristics of the environment itself are likely to impinge on health and psychological processes? When this question has been addressed within health psychology, environment has been operationalized primarily in social terms. Family and work social climates, as well as sociocultural and economic conditions, predominate in the few environmental studies in health psychology. This chapter intends to draw greater attention to the potential role of the physical environment in health and psychological processes.

Why might the physical environment be important to health psychology? For one reason, the physical environment clearly impacts health. Adverse physical conditions can cause toxicological reactions, challenge homeostatic balance, produce physical trauma, or function as vectors bearing pathogens. Physical factors can also be a source of environmental demands that pressure coping resources.

A second reason the physical environment is worthy of scrutiny within health psychology is because the environment can be modified and thus becomes a potential intervention target to improve health and well-being. Third, environmental conditions are objective and thus can be measured more readily

in reliable and valid ways. For example, researchers can systematically monitor density or noise levels in precise, accurate ways that can then be examined as possible causal factors in health. Fourth, physical environmental conditions tend to be stable. Increasingly, research suggests that chronic environmental demands are most likely to have negative impacts on health (Lepore, 1995). Finally, the concept of psychological stress that is central to several formulations of health, behavior, and disease (see chap. 17, this volume) has been utilized to broaden understanding of how physical features of the environment can influence human health and well-being.

There are at least three major ways in which the physical environment might operate as a psychological stressor, straining human adaptive capacities. First, this can occur when a stressor directly loads, or pressures, the system. Both crowding and noise, for example, create a surfeit of stimulation that can directly overload the system, causing discomfort, negative affect, and under some circumstances, the marshaling of adaptive resources. Both negative affect and adaptive responses to challenge or threat in turn directly affect neuroendocrine and cardiovascular functioning. Physical stressors can also interact with psychosocial conditions to exacerbate negative affect and/or psychophysiological mobilization. For example, noise plus high workload demands leads to more serious health outcomes than workload levels alone. Noise and crowding frequently covary with other psychosocial risk factors (e.g., poverty, inadequate working conditions), and thus have the potential to contribute to multiple risk situations.

A second manner in which the physical environment can contribute to stress is by damaging or ameliorating coping resources themselves. People rarely respond to suboptimal physical or psychosocial conditions passively; instead, they

invoke various coping strategies to reestablish some modicum of balance between environmental demands and personal resources. Evidence is presented herein, for example, that crowding interferes with the development and maintenance of socially supportive relationships in the residential environment. Both chronic noise and chronic crowding appear to contribute to learned helplessness, adversely affecting self-efficacy and related motivational processes.

The third way in which physical conditions can operate as stressors is to elicit coping strategies that in turn lead to poor health. Studies of noise, for example, reveal that increases in substance abuse occur under noisy working conditions.

Another aspect of research on psychological stress and health relevant to this chapter on environmental stressors are the concepts of vulnerability and resilience (Cohen, Kessler, & Gordon, 1995; Rutter, 1983). Just as certain personal or situational characteristics can render individuals more or less vulnerable to social stressors, there is evidence of vulnerable subgroups among the population who appear more adversely affected by noise and by crowding, respectively. Thus throughout both direct, main effects and associations between environmental stressors and health, as well as occasions with vulnerable subgroups, are noted.

The field of environmental stress (Cohen, Evans, Stokols, & Krantz, 1986; Evans, 1982; Evans & Cohen, 1987) is sufficiently developed such that exhaustive coverage is impossible. A small amount of environmental stress research has examined climatic conditions as potential psychological stressors influencing human stress responses (Bell & Greene, 1982; Evans, 1994). Research on housing conditions as a possible stressor have also been undertaken (Freeman, 1984). The focus of this chapter is on the two most studied environmental stressors, crowding and noise. Health outcomes include physical health and psychological health. Moreover, the chapter examines underlying psychosocial and psychophysiological processes that may help explain the linkages between noise and crowding and major physical and psychological health outcomes. Psychophysiological mechanisms, immune function, social resources, coping strategies, and motivational processes are examined.

CROWDING

The element of crowding that relates most strongly to physical and psychological health is people per room. Traffic congestion may also prove to be a potent stressor. Area measures of crowding, such as people per acre, generally have little or no relation to health. Although some studies of crowding separate group size effects from density effects, the vast majority of studies have confounded these two factors, manipulating or measuring density as it covaries with group size. Therefore, some of the effects attributed to crowding may be due to group size rather than the amount of space per person. At the same time, when attempts have been made to distinguish between these related concepts, density and group size, the impacts of density typically persist.

Physical Health

Early interest in crowding in the public health field emanated from concerns about the spread of disease among crowded populations (Cox, Paulus, McCain, & Karlovac, 1982). There is a large literature on this topic. Physical health has been operationalized in this literature as rates of illness based on archival data, visits to infirmary, physical development among children, and self-reports of somatic symptoms. Archival evidence for positive associations between crowding and ill health come from studies in prisons (McCain, Cox, & Paulus, 1976; Paulus, 1988), refugee camps (Arnow, Hierholzer, Higbee, & Harris, 1977), and schools (Essen, Fogelman, & Head, 1978; Koopman, 1978). The Arnow et al. (1977) study is noteworthy because they demonstrated good correlation over time between Vietnamese refugee camp population fluctuations with changes in a highly contagious disease (acute conjunctivitis). There is also evidence that crowded residential conditions are linked to disease both among children (Booth & Johnson, 1975; Jacobson, Chester, & Fraser, 1977) and among adults (Levy & Herzog, 1978; McGlashen, 1977; Menton & Meyers, 1977; Sims, Downham, McQuillin, & Gardner, 1976; Wyndham, Gonin, & Reid, 1978; Yarnell, 1979). Yodfat, Fidel, Cohen, and Eliakim (1979) found that linkages among residential crowding and asthma were due to number of children rather than density per se. Booth (1976) found that male adults, but not women, had greater levels of disease in crowded homes. Traffic congestion levels among commuters is also associated with illness-related absenteeism from work (Novaco, Stokols, & Milanese, 1990).

Several studies of residential crowding find little or no correlates with disease (Brett & Benjamin, 1957; Collette & Webb, 1974; Mackintosh, 1934; McKinlay & Truelove, 1947; Quinn, Lowry, & Zwaag, 1978), and Winsborough (1965) uncovered an inverse relation between areal density and tuberculosis. Schmitt and colleagues also found no relation between residential density and disease rates, but found small, positive correlations with areal density (people per acre) measures (Schmitt, 1966; Schmitt, Zane, & Nishi, 1978). Similar trends have been uncovered by Levy and Herzog (1974). Kellett (1984) made the important point that certain diseases should be expected a priori to correlate with crowding more so than others. Kellett examined mortality patterns for specific diseases in London for a 5-year period. As in prior work, persons per room rather than people per acre appeared more useful in predicting mortality. Second, diseases wherein a major stress component is believed to be operative (e.g., hypertension, myocardial infarction, vascular disorders, asthma) were related to household crowding whereas many other diseases (e.g., various forms of cancer) were not.

Freedman and colleagues challenged many of these studies of crowding and disease, noting that poor or nonexistent controls for other variables such as socioeconomic status are common in the crowding and epidemiological literature. They found in a well-controlled epidemiological analysis that residential crowding was not a significant predictor of disease (Freedman, Heshka, & Levy, 1975). However, the prison

studies and a few of the residential studies (e.g., Menton & Meyers, 1977) do have good controls for SES. Furthermore, there are trends in the data indicating that when individual levels of exposure to density and individual indices of health are compared rather than aggregated population statistics, such as used by Freedman and colleagues, stronger results occur. Nonetheless, Freedman and colleagues' cautious perspective on crowding and disease is well taken. Overall findings are suggestive but not rigorously or consistently supportive of a crowding-disease link. It would be useful to include, in the same individual-based study, disease rates for disorders that ought to vary with stress exposure plus inclusion of immunological measures.

A handful of studies in institutional contexts have examined crowding and infirmary visits. These studies converge on positive associations between levels of crowding and infirmary visits among shipboard military personnel (Dean, Pugh, & Gunderson, 1975, 1978), college campus residents (Baron, Mandel, Adams, & Griffen, 1976; Stokols, Ohlig, & Resnik, 1978), and prisoners (Paulus, 1988). The prison effects were most noticeable among inmates forced to live under dormitory-like conditions rather than in single cells. Trends also indicated that the associations in prisons were somewhat stronger for men than women and for African American in comparison to Anglo prisoners (Paulus, 1988). Wener and Keys (1988) found that increases in density (doubling up cell mates) markedly elevated (nearly 50%) sick call rates among prison inmates.

A few studies have examined physical development among crowded children, uncovering evidence of negative associations between household density and physical stature (Booth, 1976; Essen et al., 1978; Goduka, Poole, & Aotaki-Phenice, 1992). Crowded children, particularly boys, are shorter. Shapiro (1974) also found that boys, but not girls, motoric development appeared to be inhibited in crowded homes. Moreover, this effect was amplified among children of less educated mothers. More recently, Widmayer and colleagues (1990) found delayed psychomotor development among infants as a function of household density, controlling for socioeconomic status (SES).

Self-reported levels of physical illness are positively associated with crowding in prisons (Cox, Paulus, & McCain, 1984; McCain et al., 1976), among college dormitory women but not men (Karlin, Epstein, & Aiello, 1978), and among crowded home settings (Gove & Hughes, 1983)—although Booth (1976) found this association among men, but not women, in crowded homes. Giel and Ormel (1977) and Baldassare (1979) failed to replicate the association between home crowding levels and self-reported illness. The validity of all the self-report data on illness and crowding is suspect given retrospective self-report indices. On the other hand, Cox et al. (1984) found a dose-response function between number of inmates per cell and self-reported illness levels among male prisoners. Of additional interest, Gove and Hughes (1983) provided some evidence that heightened illness levels associated with crowded residences are related to lack of sleep and lower resistance when exposed to other sick family members (all self-reported).

There is evidence that some of the association between crowded living conditions and self-reported health symptoms is mediated by loss of perceived control over the living environment. Ruback and associates found that both female and male prisoners' reports of ill health in association with crowding were also negatively related to perceived control (Ruback & Carr, 1984; Ruback, Carr, & Hopper, 1986). Another way in which environmental stressors like crowding can impinge on health is through injuries. Rhesus monkeys when crowded, for example, show a 5-fold increase in incidents of injuries (Boyce, O'Neill-Wagner, Price, Haines, & Suomi, 1998).

Psychophysiological

Several studies have examined the relation between crowding and blood pressure in people. Laboratory studies with random assignment to density levels have found small but significant elevations among crowded versus uncrowded participants (Epstein, Lehrer, & Woolfolk, 1978; Evans, 1979). Field studies of prisoners (D'Atri, 1975; Paulus, McCain, & Cox, 1978) and automobile commuters (Novaco, D. Stokols, Campbell, & J. Stokols, 1979; Schaeffer, Street, Singer, & Baum, 1988; Stokols et al., 1978) have also revealed correlational evidence for elevated blood pressure under more crowded or congested living or commuting conditions. The commuting studies have found that the effects are stronger for car poolers rather than solo drivers, for Type B rather than Type A drivers, among external versus internal locus of control drivers, and among drivers with less residential choice. One field study found no relations between chronic residential crowding and blood pressure or neuroendocrine indices among adults (Booth, 1976), although small, statistically significant elevations in serum cholesterol were noted among crowded men. No such correlation was noted among women. Booth's sample did not vary much in density, which may have weakened his findings. Evans, Lepore, Shejwal, and Palsane (1998) found elevated blood pressure among crowded boys, but not girls, among working-class families in India.

Another cardiovascular function, blood pressure reactivity, has been related to chronic crowding in adults. Residents of more crowded neighborhoods had higher reactivity (increase from baseline in blood pressure levels) and took longer to return to resting baseline levels (Fleming, Baum, Davidson, Rectanus, & McArdle, 1987). Both heightened reactivity and protracted recovery to baseline are potentially important precursors to the development of coronary heart disease.

Neuroendocrine markers of stress, typically urinary catecholamines and cortisol, have been noted in several studies of crowded commuters (Lundberg, 1976; Singer, Lundberg & Frankenhaeuser, 1978) and among bus drivers operating under more congested driving conditions (Evans & Carrere, 1991).

Pedestrian exposure to more crowded urban areas elevates neuroendocrine activity, at least for males (Heshka & Pylypuk, 1975), and residence in neighborhoods perceived as more crowded because of commercial establishments and more people on the street is associated with increased urinary catecholamine levels (Fleming, Baum, & Weiss, 1987). Dor-

mitory crowding, however, had no apparent effects on neuroendocrine activity among college students (Karlin et al., 1978). A small sample size may have rendered low power. These authors did find, however, that uncrowded residents' neuroendocrine indices dropped over the course of the semester, whereas crowded residents' neuroendocrine levels increased over the same time period. Schaeffer, Baum, Paulus, and Gaes (1988) found that prisoners housed in more open, unpartitioned dormitories felt more crowded and experienced elevated chronic catecholamine levels in comparison to prisoners living in smaller groups.

The critical role of control has been implicated in some of these psychophysiological crowding studies. Lundberg (1976) and his colleagues found that passengers with greater choice over seating were less negatively impacted by congested commuting. Evans and Carrere (1991) found that the neuroendocrine effects of traffic congestion on bus drivers were largely mediated by perceived control on the job. On the other hand, perceived control did not mediate the positive relation between prison crowding and neuroendocrine elevations (Schaeffer, Baum, Paulus, & Gaes, 1988).

A few laboratory studies have also utilized skin conductance as an index of psychophysiological stress, generally finding elevations among more crowded participants (Aiello, Epstein, & Kalin, 1975; Aiello, Nicosia, & Thompson, 1979; Bergman, 1971; Nicosia, Hyman, Karlin, Epstein, & Aiello, 1979). Studies of crowding and skin conductance are evenly split on gender differences, with some studies finding more pronounced effects among males than females and other studies finding no sex differences. There is also evidence that skin conductance may be more strongly affected by crowding when physical touching occurs. McCallum, Rusbult, Hong, Walden, and Schopler (1979) found that acute crowding elevated palmar sweat but only when experimental subjects were motivated to maintain high levels of group performance. When performance was permitted to deteriorate under crowding, no physiological elevations were noted. Finally, in a field study, Cox, Paulus, McCain, and Schkade (1979) found a significant positive correlation between the palmar sweat index and crowding among prison inmates.

Although indirect, some findings by Hutt and Vaizey (1966) may shed some light on psychophysiological mechanisms associated with crowding and psychophysiological responses. Chronically overaroused children responded to high density laboratory conditions by extreme social and physical withdrawal; whereas chronically underaroused children and children without arousal disturbance reacted in the opposite direction, becoming more engaged and aggressive with other children.

Many animal studies have examined endocrine activity among crowded species both under laboratory and field conditions (see Evans, 1978, for a review). Generally, this research indicates support for a population regulation feedback mechanism whereby crowded animals' fertility declines. This occurs more markedly among subordinate rather than dominant animals and appears to be mediated by adrenal cortical activity. Attempts to link crowding with population regulation among human beings have proven futile.

Immune Function

Animal but not human work has examined immunological processes as a function of crowding, generally finding evidence of compromised immune functioning among more crowded animals (Christian, 1963; E. A. Edwards & Dean, 1977; Thiessen & Rodgers, 1961). These effects appear to be stronger among subordinate rather than dominant animals and among animals without a history of crowded living conditions (Cassel, 1971). Cassel (1974) pointed out, however, that compromised immune function alone cannot account for changes in morbidity among crowded animals because both infectious and noninfectious diseases are elevated among crowded animals.

Psychological Health

Ever since 1962 when Calhoun published his famous *Scientific American* study of pathology among overpopulated rats, researchers and policymakers alike have wondered about the potential role of crowded living conditions on mental health. The chapter first reviews research on linkages between density and psychological distress and then turns its attention to recent work examining possible underlying mechanisms for this linkage.

Many studies have uncovered positive relations between residential density and self-reported psychological distress (Edwards, Fuller, Sermsri, & Vorakitphokatorn, 1990; Evans, Palsane, Lepore, & Martin, 1989; Gabe & Williams, 1987; Gove & Hughes, 1983; Hassen, 1977; Jain, 1987; Lakey, 1989; Marsella, Escudero, & Gordon, 1970). Mitchell (1971) found greater worrying among crowded families but only if they were also poor. Crowding in Mitchell's study was unrelated, however, to more serious indices of psychiatric illness. Lepore, Evans, and Schneider (1991) found evidence that residential crowding causes psychological distress in a prospective, longitudinal study of crowding and mental health. Controlling for educational levels and income, they found that crowded residents did not differ from uncrowded residents in psychological distress symptoms during initial occupancy ($r = .12$), but after 2 months and 8 months the associations became significant ($r = .21$; $r = .27$). This is the only prospective study of crowding and health. Webb and Collette (1975) found an association between residential density and use of prescription hypnotics.

Booth (1976), Baldassare (1979), and Giel and Ormel (1977) failed to find a positive association between residential crowding and psychological distress. These studies had little variance in density. Moreover, Baldassare relied on mental health indices of questionable sensitivity (one dichotomous item in one case, and three dichotomous items in a second case). Two studies of neighborhood crowding levels have also found linkages to psychological distress (Collette & Webb, 1974; Fleming, Baum, & Weiss, 1987).

Studies utilizing archival indices such as psychiatric admissions or suicide rates generally find very weak or insignificant associations between crowding and pathology when measured in the aggregate (Freedman et al., 1975; Gove &

Hughes, 1980; Schmitt, 1966; Schmitt et al., 1978). In some studies negative associations between density and psychiatric admissions have been uncovered, probably created by the association of living alone and mental disorder (Galle, Gove, & McPherson, 1972; Levy & Herzog, 1974, 1978). One exception to these generally negative trends in archival indices of mental health and crowding is notable. Several prison studies have found clear, strong associations between the total population size of prison populations and indices of psychiatric illness (Paulus, 1988).

Quite a number of studies have examined psychological symptoms among children living in crowded homes. Plant (1937) described several case studies noting a pattern of low self-sufficiency and little idealism among children from crowded homes. He attributed these patterns to mental strain associated from always having to get along with others and to exposure to adults under close quarters that made it difficult to look up to or idealize grownups. Crowded children have increased levels of various symptoms of psychological distress (Booth, 1976; Gasparini, 1973; Murray, 1974; Saegert, 1982; Wachs, 1987). Parents in more crowded homes report relief when their children are outside (Gove & Hughes, 1983), have more difficulty supervising their children (Mitchell, 1971), and are generally less responsive and involved with their children (Bradley & Caldwell, 1984; Evans, Maxwell, & Hart, 1999; Wachs & Camli, 1991) in comparison to uncrowded parents of comparable social class. These trends appear to be exacerbated in the presence of other risk factors, particularly poverty (Baldassare, 1981; Bradley et al., 1994).

Psychosocial Resources

Some of the relation between high residential density and psychological distress in children may be linked to family interactions, which have been found to be more contentious under crowded living conditions (Booth, 1976; Gasparini, 1973; Saegert, 1982). There may also be greater incidence of physical punishment and open expression of anger between parents and children in crowded homes (Booth & Edwards, 1976; Light, 1973), although Gove and Hughes' (1983) study did not support this finding.

Another factor that may help explain the link between high residential crowding and symptoms of psychological distress in children is withdrawal. Aiello, Thompson, and Baum (1985) reviewed several field and laboratory studies documenting increased social withdrawal under crowded conditions among young children. Similar trends exist in the adult literature, indicating that crowded adults interact with housemates less (Baum & Valins, 1977, 1979; Proshansky, Ittelson, & Rivlin, 1970); are less friendly with their neighbors (McCarthy & Saegert, 1978), and have impaired social support with those they live with (Evans et al., 1989; Lakey, 1989; Lepore et al., 1991). Baldassare (1979) did not replicate linkages between residential crowding and neighboring. People under crowded conditions also tend to be less affiliative in their behaviors toward others (R. L. Munroe & R. H. Munroe, 1972) and view others in more negative or suspicious terms (Bickman et al., 1973; Grifit & Veitch, 1971; McCarthy &

Saegert, 1978). There is also evidence that crowded working conditions lead to greater social withdrawal from coworkers (Oldham & Fried, 1987). Finally, as already noted, parents in crowded homes are less responsive to their children (Bradley & Caldwell, 1984; Wachs & Camli, 1991). Furthermore, this relative unresponsiveness partially accounts for less complex parent to child verbalizations to infants and toddlers (Evans, et al., 1999).

Evidence that social withdrawal and impaired social relationships are a primary mechanism accounting for the relation between crowding and psychological distress has been documented in some detail by two research programs. Baum and colleagues found that more crowded dorm residents report more unwanted social interaction in their dorms. These same crowded residents also evidence greater behavioral indices of withdrawal outside of the dorm. They sit farther away from other research participants and withdraw more in group interaction games (Baum & Valins, 1977, 1979). Residential exposure to high levels of street traffic is also associated with less neighboring (Appleyard & Lintell, 1972; Halpern, 1995). Evans and Lepore showed direct evidence for a similar pattern. They found both cross-sectionally (Evans et al., 1989) and in a prospective, longitudinal design (Lepore et al., 1991) that the negative effects of residential crowding on psychological distress (with controls for social class) are mediated by social support. Similar patterns also appear to occur among children in crowded residences (Evans, et al., 1998).

Evans and Lepore (1993a) also found that crowded relative to uncrowded residents were less likely to offer support to a confederate under stress in an uncrowded laboratory setting. Of additional interest, crowded residents in comparison to uncrowded residents were also less responsive to offers of social support during a stressful situation (see Fig. 20.1). *Ignored* meant that the subject did not look at or made no verbal acknowledgment of the confederate; *acknowledgment* meant some brief comment or a head nod was given in response to offers of support; and *accepted* meant the subject was very re-

FIG. 20.1

sponsive to the confederate's offers of support, elaborating or embellishing on their offers of support.

Motivation

Many theorists have postulated that a prime reason why crowding can have negative impacts on psychological health is because of reduced behavioral options and greater difficulty in regulating social interaction (Altman, 1975; Baron & Rodin, 1978; Schmidt & Keating, 1979). An important psychological consequence of prolonged exposure to an aversive, uncontrollable stressor, such as crowding, may be learned helplessness. Persons chronically exposed to crowding report feeling a greater sense of powerlessness over their living environments than their less crowded counterparts (Baum & Valins, 1977, 1979; Baron et al., 1976; Carr, Hopper & Ruback, 1986; Saegert, 1978). Sherrod (1976), Aiello, DeRisi, Epstein, and Karlin (1977), Evans (1979), Nicosia et al. (1979), and Dooley (1978) all found negative aftereffects immediately following laboratory exposure to crowded conditions. Sherrod, Evans, and Nicosia and colleagues each utilized the Glass and Singer (1972) aftereffects paradigm that measures persistence on challenging puzzles. Giving up sooner in the face of challenge in an achievement context may be indicative of greater helplessness (Cohen, 1980; Glass & Singer, 1972). Dooley (1978) incorporated proofreading performance as her aftereffects measure. Saegert, Mackintosh, and West (1975) reported that crowded train stations produced negative aftereffects in women only. Nicosia's data also indicated more severe aftereffects of crowding among women.

Parallel trends to the laboratory work have been noted in studies of more chronic, crowded living conditions, finding less persistence on difficult puzzles among persons living in more crowded neighborhoods (Fleming, Baum, & Weiss, 1987). Moreover, perception of control over social interactions largely accounted for the main effect of neighborhood crowding on the helplessness indicator. Residents of crowded dorms feel less control over social interaction than their uncrowded counterparts (Baum & Valins, 1977, 1979) and exhibit behavioral strategies in a group prisoners' dilemma game consistent with helplessness (Baum, Aiello, & Calesnick, 1978; Baum, Gatchel, Aiello, & Thompson, 1981). Interestingly, the development of helplessness strategies in the game over the course of the initial semester under crowded conditions was mirrored by residents growing external attributions for problems in the dormitory over this same time period (Baum et al., 1981). Uncrowded residents generally felt self-efficacy over problems in their dormitory over the course of the semester and these internal attributions remained stable over time. Crowded dormitory residents are also less likely to seek clarification when given ambiguous instructions about an impending laboratory procedure than were uncrowded dormitory residents.

Traffic congestion also is related to motivational deficits. Greater traffic congestion levels have been related to decreased task motivation on challenging puzzles and proofreading (Novaco et al., 1979; Schaeffer et al., 1988; D. Stokols, et al., 1978).

The most direct evidence for helplessness induced by crowding comes from a pair of studies on residential crowding and children by Rodin (1976). Matched on socioeconomic indicators, elementary-aged schoolchildren living in more crowded public housing were less likely to control the administration of outcomes in an operant conditioning paradigm in comparison to their less crowded counterparts. In a second study, helplessness was induced in adolescents by a classic helplessness paradigm, pretreatment with an insoluble versus a soluble puzzle. Helplessness was monitored on a second challenging but solvable puzzle. The main effect of pretreatment solvability (the helplessness induction) was significantly moderated by residential crowding with heightened vulnerability to the induction of helplessness among the more crowded children. In their study of children in India, Evans, et al., (1998) replicated Rodin's effects (but for girls only). Saegert (1982), however, did not replicate these findings examining a sample of children from public housing projects in New York City.

Summary

Residential crowding has little impact on physical morbidity among the general population. Residential crowding may be linked, however, to ill health among vulnerable subgroups of the populations, particularly young children and extremely crowded, captive populations (e.g., prisons, refugee camps). Evidence linking high density exposure either under controlled conditions or in the field to elevated cardiovascular functioning is quite strong. Neuroendocrine functioning also appears elevated, although less data are available. The potential clinical implications of these two data patterns has not been explored in the crowding literature.

Psychological distress is increased by residential crowding. Individual but not aggregate level analyses continue to uncover a positive association between crowded living conditions and poorer psychological health. Several studies have excellent controls for sociodemographic factors and one is a prospective, longitudinal analysis. Psychological distress associated with residential crowding may be caused by a typical coping strategy for dealing with chronic high density living conditions—social withdrawal. An unintended consequence of this social withdrawal may be a breakdown in socially supportive relationships. There is not strong evidence, however, that human crowding is associated with more extreme forms of psychopathology characterized in some animal studies as a behavioral sink.

There is also evidence that crowding may lead to the development of motivational deficits, particularly among children in achievement-related contexts. There is indirect evidence suggesting that these motivational deficits are related to learned helplessness from diminished perceived control over the environment.

NOISE

Noise, which is defined as unwanted sound, is typically measured in decibels. Decibels is a logarithmic scale with a

change in 10 decibels perceived as approximately twice as loud. There is considerably more research on noise and health in comparison to research on crowding and health. The bulk of the noise and health research has occurred in industrial settings. More recently, studies of noise and health have also focused on people living in airport impact zones or near to road traffic noise. Prolonged exposure to high levels of noise is clearly linked to hearing damage (Kryter, 1994). Because the thrust of this chapter is on environmental stress, the noise-related hearing damage literature is not discussed.

Physical Health

Studies have examined exposure to either occupational noise or community noise and disease. Outside of cardiovascular problems, there appears to be little relation between noise exposure and physical disease. In industrial settings, noise has been associated with increased risk for myocardial infarction (Ising, Babisch, & Günther, 1999), reductions in cardiorespiratory efficiency (Semczak & Gorny, 1971), difficulties in peripheral circulation and cardiac problems generally (Jansen, 1961), electrocardiogram abnormalities suggestive of coronary heart disease (Cuesdan et al., 1977), general sickness-related absenteeism (Cohen, 1973), and self-reported fatigue (Carlestam, Karlsson & Levi, 1973; Melamed & Bruhis, 1996). Several industrial studies have found no associations between occupational noise exposure and rates of coronary heart disease (Lees, Romeril, & Wetherall, 1980) or rates of total illness (Lees et al., 1980).

Community airport noise studies have shown that higher levels of noise exposure are associated with greater contact with physicians for coronary-related problems (Knipschild, 1977a) and, for women only, use of drugs to treat hypertension (Knipschild & Oudshoorn, 1977; Koszarny, Maziarka, & Szata, 1981). These studies also show an association with greater physician contact in general (Knipschild, 1977b), rates of colds (Ising et al., 1990), as well as total health symptoms (Pulles & Stewart, 1990), and higher levels of coronary heart disease symptoms among women but not men (Koszarny et al., 1981). Graeven (1974) and Hiramatsu, Tamamoto, Taira, Ito, and Nakasone (1993), however, found no differences in self-reported health symptoms between persons living in airport impact zones versus citizens in quiet neighborhoods.

Turning to road traffic noise, Cameron, Robertson, and Zaks (1972) found little relation between community noise levels (self-reported) and illness rates. Babisch, Elwood, Ising, and Kruppa (1993) found slight elevated risk (1.2 odds ratio) in noisier traffic areas in three different sites for men residing in areas above 65 dBA Leq. However, when comparing across different noise levels varying from > 50 dBA Leq to 70, they uncovered no linear relation.

Another area of physical health worthy of note in the noise literature is birth defects and other abnormalities during pregnancy. Not surprisingly, findings in this area are highly controversial and not at all definitive. Jones and Tauscher (1978) found higher rates of birth defects in high airport noise impact zones relative to quieter areas, but Edmonds, Layde, and

Erickson (1979) could not replicate the findings. Several rodent studies have found abnormal fetal development following noise exposure (Welch, 1973). There is evidence that women working under very noisy conditions, particularly if subjected to additional stressors like shiftwork, have more pregnancy complications such as vaginal bleeding and pregnancy-induced hypertension (Nurminen & Kurppa, 1989). Babies born in areas with high noise impact have lower birth weights (Ando & Hattori, 1977; Knipschild et al. (1981) with controls for socioeconomic status. Ando (1987) also found an increase in low birth weight babies following the opening of a new airport. Schell (1981) also noted that female infants, but not males, had significantly shorter gestation periods in high airport noise impact zones. Moreover, Ando and Hattori (1977) showed diminished levels of human placental lactogen levels in mothers living in high noise airport impact zones. Finally, Schell and Ando (1991) found a dose-response function relating airport noise levels and 3-year-olds' physical stature (but not weight) in a large epidemiological study. The data on possible linkages between noise and early development are sobering to consider in light of environmental surveys of neonatal, intensive care units that are often populated by premature babies. Levels of noise match or exceed recommended standards for ambient traffic exposure and health (Lawson, Daum, & Turkewitz, 1977).

Psychophysiological

Although previous reviews of noise indicate that cardiovascular responses (typically blood pressure or pulse) to noise under acute exposures rapidly habituate (Glass & Singer, 1972; Kryter, 1994), more careful scrutiny of this literature indicates important exceptions. Persons who are noise sensitive do not easily habituate (Conrad, 1973; Stansfeld & Shine, 1993), nor do individuals who are hypertensive (von Eiff, Friedrich, & Neus, 1982). Short-term habituation is blocked when people perform demanding cognitive tasks under noise (Carter & Beh, 1989; Conrad, 1973; Mosskov & Ettema, 1977). Evans et al. (1996) also showed that noise significantly increases blood pressure over a 20-minute period without habituation, if it follows exposure to a psychological stressor (i.e., giving a speech, taking a final examination).

Other psychophysiological indices examined under acute noise have included electrodermal activity, ECG, EEG, and neuroendocrine activity. Results parallel the cardiovascular data, indicating rapid habituation (Finkle & Poppen, 1948; Fruhstorfer & Hensel, 1980). Recent findings suggest, however, that when short-term exposure to loud noise is accompanied by demanding tasks, habituation may be blocked (Frankenhaeuser & Lundberg, 1977; Ising, Rebentisch, Poustka, & Curio, 1990; Lundberg & Frankenhaeuser, 1978). Work by Tafalla and Evans (1997) indicated a central role of effort in the performance/physiological activation tradeoff. Performance can be maintained, at least under many circumstances (e.g., short-term tasks that do not demand large amounts of attention or memory), by additional cognitive effort. Such maintenance of performance, however, appears to exact a cost of greater psychophysiological

activation. It is noteworthy that McCallum et al. (1979) found a very similar pattern for performance under crowded laboratory conditions.

There is also evidence indicating that habituation is interfered with by calling attention to the potential negative impacts of noise on the person (Vera, Vila, & Godoy, 1992). This latter finding might explain why noise sensitive persons apparently do not readily habituate to repeated exposures of acute noise in the laboratory. Perhaps they are more threatened or concerned about potential harmful effects of the noise.

Field research on noise and psychophysiologic outcomes has occurred primarily in industrial settings. The occupational noise and psychophysiologic literature is too large to review exhaustively herein. Several reviews of this literature (Kryter, 1994; Thompson, 1981, 1993; Welch, 1979) have characterized the findings similarly. Unfortunately, nonexperimental designs have frequently been employed in the occupational noise and health literature with poor or nonexistent controls, and many studies have relied on poor estimates of noise exposure. Furthermore, blood pressure is often poorly measured. Many of the industrial studies have relied on one or two measures of blood pressure taken during a physical at work by medical personnel. Moreover, annual medical examinations or other medical screenings may seriously bias estimates since some workers become excluded.

Thompson concluded from her two reviews that workers with adequate hearing protection are unlikely to show much effect of noise on the cardiovascular system. Kryter (1994) reflected greater concern but also remained skeptical, noting the paucity of well-designed research studies; Welch (1979) sounded a considerably greater sense of alarm about cardiovascular health risks from chronic, occupational exposure to noise. Interestingly, Welch's review is based primarily on Eastern European literature that includes worksites with generally very high levels of occupational noise exposure, often coupled with a paucity of hearing protection programs. The bulk of the literature in the other major reviews is based on North American and Western European studies where occupational noise levels tend to be lower and hearing protection programs more common.

Difficulties in exposure estimation in industrial studies of noise and cardiovascular functioning are illustrated by one of the most thorough investigations (Talbot et al., 1985). Although these investigators found no significant differences in blood pressure readings that were carefully administered to men from noisy and from quiet manufacturing plants, they also uncovered a clear, consistent positive link between elevated diastolic blood pressure and severe hearing loss in the noisy plant. Moreover, looking at the subset of men who had worked for at least 15 years in the two respective manufacturing plants, occupational noise exposure did significantly relate to both systolic and diastolic blood pressure (Talbot et al., 1990). See Lercher (1996) for an in-depth discussion of noise exposure estimation and health outcomes.

It is also conceivable that subsets of workers may be particularly vulnerable to the chronic effects of noise exposure on their cardiovascular systems. For example, Tarter and Robins (1990) found that male, African American automobile plant

workers suffered increased blood pressure, whereas their Anglo counterparts, who were exposed to comparable levels of high noise at work, did not show this relation. Tarter and Robins speculated that perhaps racial differences in propensity for hypertension might explain these findings. Given the fact that individual differences in noise sensitivity interfere with habituation to acute noise exposure as reviewed earlier, it might be hypothesized that noise sensitivity creates vulnerable subgroups within occupationally noise-exposed groups. This idea has not been tested, although mixed support of such a pattern has been uncovered in community studies of aircraft noise (Neus, Ruddel, & Schulte, 1983; Stansfeld, 1993).

A few longitudinal studies of noise and cardiovascular functioning in industrial settings have been conducted. By comparing the same worker in quiet and noisy periods, some of the weaknesses most endemic to cross-sectional studies (e.g., selection bias) are reduced. The U.S. Raytheon (1975) study, for example, found a significant reduction in medical problems after the implementation of a hearing conservation program in the plant. No changes in similar health indices occurred over the same time period among workers in quiet plant areas. Moreover, the greater the level of compliance observed (e.g., wearing hearing protection), the greater the apparent health benefit. Hypertension and cardiovascular disease were included in the overall health records monitored but could not be singled out because of insufficient sample size. Antonova (1971) compared miners before and after their workshifts in either noisy or quiet areas of the mine. Noise significantly elevated mean arterial pressure with no changes in the quiet group pre and post work. Systolic blood pressure was significantly elevated among brewery workers when they did not wear ear plugs in comparison to days in which they did (Ising & Melchert, 1980). Cortisol fluctuations were also shown to be dependent on the use of earplugs in a similar design (Melamed & Bruhis, 1996).

Another more rigorous approach to studying industrial noise exposure and psychophysiological responses is to simulate occupational noise exposure under experimental conditions with random assignment to noise conditions. Three-hour exposure to jet turbines significantly elevated blood pressure over resting levels among workers in a jet assembly plant (Ortiz, Arguelles, Crespini, Sposari, & Villafane, 1974). Mosskov and Ettema (1977) and Rovekamp (1983) found elevations in blood pressure in 2- to 3-hour noise exposures but at much lower intensities of noise than employed by Ortiz and colleagues. Cartwright and Thompson (1975) found no effects, however, of a 1-hour exposure to loud noise, but Carter and Beh (1989) were able to significantly elevate cardiovascular parameters from 1 hour of exposure, as long as participants simultaneously worked at a difficult task.

This latter finding, along with other experimental findings reviewed earlier on the multiplicative effects of noise and task demands on cardiovascular and neuroendocrine functioning, is interesting to consider in light of a small number of occupational noise studies that have also incorporated additional measures of working conditions. A Russian industrial study reviewed by Welch (1979) found elevated cardiovascular functioning in a noisy manufacturing plant among workers

with higher levels of workload demands. Workers with low workloads did not reveal any cardiovascular correlates of occupational noise exposure. Parallel results were recently uncovered in a longitudinal study (Melamed, Boneh-Kristal, & Froom, 1999). Cottington, Matthews, Talbott, and Kuller (1983) also reported a significant interaction of job stress and noise on diastolic blood pressure. Job stress was associated with higher blood pressure in a noisy manufacturing plant but not a quiet one with good controls for SES and cardiovascular risk. Similarly, Lercher, Hortnagl, and Kofler (1993) found that annoyance with noise at work had a small positive association with diastolic blood pressure. This relation was significantly amplified, however, among workers who also reported job dissatisfaction and low levels of social support on the job. Occupational exposure to noise levels may also interact with shift work. Ottmann, Rutenfranz, Neidhart, and Boucsein (1987) and Cesana et al. (1982) both found elevated catecholamine levels related to noise levels at work but only among workers on rotating shifts. Nonshift workers in noisy work areas did not reveal these associations. Lercher et al. (1993) also found higher levels of blood pressure among workers annoyed by noise who also engaged in shiftwork relative to nonshiftwork employees.

There has been a small number of industrial studies or simulation studies with prolonged noise exposure that have examined neuroendocrine and other biochemical markers of stress rather than cardiovascular functioning. Mixed results have been uncovered with no relation between noise exposure and cholesterol (Brown, Thompson, & Folk, 1975), cortisol (Brandenberger, Follenius, & Tremolieres, 1977; Cavatorta et al., 1987; Slob, Wink, & Radder, 1973), and with one or more catecholamines (Carlestam et al., 1973; J. Osguthorpe, Mills, & N. Osguthorpe, 1983; Paulocci, 1975; Slob et al., 1973). Other studies have uncovered significant, although typically small, associations between noise levels on the job or from simulated exposures and various psychophysiological indicators, such as reduced urine volume and 17-ketosteroid levels (Gibbons, Lewis, & Lord, 1975), elevated fatty acids (Ortiz et al., 1974; Proniewska et al., 1972), higher levels of cholesterol (Cantrell, 1974; Ortiz et al., 1974; Rai, Singh, Upadkay, Patil, & Nayer, 1981), increased epinephrine levels (Cavatorta et al., 1987; Ortiz et al., 1974; Slob et al., 1973), elevated cortisol (Cantrell, 1974; J. Osguthorpe et al., 1983; Rai et al., 1981), and increased levels of ACTH and oxytocin (Fruhstorfer & Hensel, 1980). Although there are more published positive findings, it is important to keep in mind that most of these noise and biochemical studies find small changes, and null results are more difficult to get published. On the other hand, there is also a large animal literature generally consistent with significant biochemical outcomes from acute noise exposure under controlled conditions (B. Welch & A. Welch, 1970).

Increasingly, researchers have turned their attention to community studies of noise and psychophysiological parameters, particularly blood pressure. Traffic noise levels appear to have no relation to blood pressure in community samples (Elwood, Ising, & Babisch, 1993; Lercher & Kofler, 1993; Knipschild & Sallé, 1979) or show a small positive associa-

tion (von Eiff, Friedrich, & Neus, 1982; Neus, Ruedel, Schulte, & von Eiff, 1983; Wu, Chiang, Huang, & Chang, 1993). Regecova and Kellcova (1995) found that traffic noise both at home and at school was associated with elevated blood pressure among 3- to 7-year-olds. Interestingly, there were multiplicative effects as well of school and home noise. The Neus study is noteworthy because it is longitudinal. The Wu study bears mention as well since they found that traffic noise elevated young children's blood pressure as a function of hearing status. Congenitally deaf children were unaffected by road noise, whereas their able-hearing counterparts suffered small elevations. Herbold, Hense, and Keil (1974) noted a small positive relation between traffic noise levels and hypertension prevalence among adults and Babisch, Fromme, Beyer, and Ising (1996) found elevated overnight neuroendocrine stress hormones. Simulated exposure to traffic noise under controlled conditions elevates both cardiovascular and neuroendocrine activity as a function of sound intensity (Ising, Dienel, & Markert, 1980; Osada, Ogawa, Hirokawa, & Haruta, 1973). Ising's study is particularly interesting because, as in several of the acute noise exposure studies noted earlier, he found that exposure to simulated traffic noise while working had significant effects on both cardiovascular and neuroendocrine levels, especially when mental loads were higher. In one of the more rigorous tests of ambient noise exposure and cardiovascular health, Peterson, J. S. Augenstein, Tanis, and D. G. Augenstein (1981) were able to produce sustained, elevated arterial blood pressure in monkeys exposed for long periods of time to simulated recordings of aircraft and traffic noise played at typical ambient levels ($Leq = 78$). Their work also showed that these monkeys sustained no hearing damage.

Studies of airport noise, which is typically louder and less predictable than road traffic noise, generally find stronger associations between noise exposure and elevated cardiovascular functioning in comparison to the road traffic noise studies. Most studies have focused on children rather than adults, which might also explain the generally more consistent, positive results than those uncovered in the road traffic noise literature.

Knipschild (1977a) found a dose-response relation between community airport noise exposure and hypertension among adult residents in Amsterdam. Two studies of simulated, military aircraft flights at low altitude have shown significant increases in blood pressure among elderly residents (Michalak, Ising & Rebentisch, 1990) and in catecholamines among middle-aged adults (Maschke, Breinl, Grimm, & Ising, 1992). Several studies have found significant relations between exposure to aircraft noise and elevated blood pressure in children (Cohen, Evans, Krantz, & Stokols, 1980; Cohen et al., 1986; Evans, Hygge & Bullinger, 1995; Ising et al., 1990; Karagodina, Soldatkina, Vinokur, & Klimukhin, 1969; Karsdorf & Klappach, 1968; Schmeck & Poustka, 1993). Several of these studies have very thorough statistical controls for socioeconomic status. One study has found no relation between airport noise levels and blood pressure (Cohen, Evans, Krantz, Stokols, & Kelly, 1981), but these data were explained by selective attrition (persons in noisy areas with

the highest levels of blood pressure left the area). Roche, Chumlea, and Siervogel (1982) found no association between ambient noise exposure in suburban communities with no nearby airports or major highways. This study is flawed because of unreliable blood pressure measurement procedures and use of self-reports for noise exposure estimation.

Evans and colleagues (1995) also investigated reactivity to a noise source, as well as chronic neuroendocrine activity levels as a function of community airport noise exposure. As shown in Table 20.1, they found evidence of elevated catecholamine activity, but no shifts in cortisol among elementary schoolchildren living in the flight path of a major international airport. Of further interest, children chronically exposed to noise appeared less reactive to an acute noise source while reading.

Ising and his colleagues found parallel trends for epinephrine, but not norepinephrine, and also found elevated cortisol in two sets of studies with adults that simulated exposure to night-time aircraft operations (Maschke, Ising, & Arndt, 1995). Of additional interest, in one study they generated a dose-response function between elevated overnight hormonal levels and sound intensity levels. Finally, Evans, Bullinger, and Hygge (1998) replicated their cross-sectional aircraft noise and young children's health findings in a prospective, longitudinal study of children living in the vicinity of the new, Munich international airport.

Immune Function

A large number of animal studies have utilized noise as a stressor to investigate altered immune function. The results, like those of the few human studies are quite mixed (Bly, Goodard, & McLean, 1993). Sieber et al. (1992), for example, found that uncontrollable but not controllable noise significantly decreased natural killer cells among healthy male subjects; Weisse et al. (1990) found the opposite pattern with controllable noise causing lymphocyte resistance to mitogens to drop.

Coping Behaviors

An alternative pathway by which noise and other environmental stressors may impact physical health is the exacerbation of substance abuse. Cigarette smoking and alcohol consumption both increase under stress (Cohen et al., 1986). In the presence of loud noise, nicotine ingestion reduces muscle tension (Hutchinson & Emley, 1973) and accelerates habituation (Friedman, Horvath, & Meares, 1974). In a

particularly interesting study, Cherek (1985) demonstrated a dose-response function between cigarette smoking (objective, experimental measures) and controlled exposures to varying noise levels (60-90 dBA).

Psychological Health

Several different types of studies have examined chronic noise exposure and mental health. The first set of studies explored possible relations between psychiatric admissions and aircraft noise exposure with decidedly mixed results. Several studies have found positive correlations between admission rates and high noise exposure (Abey-Wickrama, A'Brook, Gattioni, & Herridge, 1969; Herridge & Chin, 1972; Jenkins, Tarnopolsky, & Hand, 1981; Meecham & Smith, 1977). Nonsignificant relations have been found by Gattioni and Tarnopolsky (1973), and Jenkins, Tarnopolsky, Hand, and Barker (1979) found an inverse relation between noise levels and psychiatric admissions in the same region (Heathrow, to the West of London) utilized by Abey-Wickrama and by Jenkins et al. (1981). Kryter (1990), in a further analysis of some of Jenkins' data, discovered large ethnic differences that might have explained Jenkins' puzzling findings. Many of these studies have poor controls for social class and all are cross-sectional.

Self-reports of psychological distress were unrelated to road traffic noise levels in two cross-sectional studies (Tarnopolsky & Morton-Williams, 1980; Tarnopolsky, Watkins, & Hand, 1980) and in a prospective, longitudinal study (Stansfeld, 1993). The absence of support for a link between road traffic noise exposure and psychological health could be due, in part, to noise measurement. Halpern (1995) found that peak noise levels predicted several indices of psychological health, controlling for socioeconomic status of residents. Mean levels of traffic noise had no mental health correlates. Physician treatment for psychological problems, as well as use of hypnotic drugs, was associated with aircraft noise around Amsterdam (Knipschild, 1977b). Koszarny et al. (1981) demonstrated a similar relation, but only among women. Knipschild and Oudshoorn (1977) also found a clear relation among prescription rates for tranquilizers and aircraft noise over a 7-year period. Moreover, these authors found longitudinal trends in use of hypnotic pharmaceuticals that tracked changes in noise levels in airport impact zones. At the same time, they noted lower and consistently similar utilization rates among quiet neighborhoods of comparable socioeconomic composition. Grandjean, Graf, Lauber, Meier, and Muller (1976) found a dose-response function linking airport noise exposure to self-reported use of sleeping pills and tranquilizers. Watkins, Tarnopolsky, and Jenkins (1981), however, could not replicate the linkages between drug usage and aircraft noise exposure. One study has also uncovered a coarse dose-response function between occupational noise exposure and psychological symptoms among blue-collar workers (McDonald, 1989). Interestingly, in light of earlier work on crowding, social support and psychological health, Mc Donald also noted that impaired interpersonal relationships at work appeared to play a role in the mental health-noise links.

TABLE 20.1
Twelve-Hour, Overnight Neuroendocrine Measures

Variable	Quiet	Noisy
Epinephrine	368.62 ng/hr	526.36 ng/hr
Norepinephrine	766.22 ng/hr	1,108.82 ng/hr
Cortisol	3.62 ug/hr	3.75 ug/hr

Motivation

Interestingly, the initial study of helplessness and human beings utilized inescapable noise as the induction stimulus. Hiroto (1974) demonstrated that short-term exposure to inescapable noise induces helplessness. Adults were exposed to noise or quiet during an initial phase of an experiment. Half of the noise subjects could avoid the noise by learning an avoidance response. For the other half of the noise subjects, the noise was inescapable. The groups were then tested in a similar situation where noise could easily be avoided by a simple manual response. A second series of experiments replicated Hiroto's findings and also demonstrated that the helplessness induced by inescapable noise generalized to persistence on subsequent task performance (Hiroto & Seligman, 1975). Subjects exposed to inescapable noise exhibited significantly greater helplessness in the second testing phase, regardless of the similarity of the helplessness induction and testing phase (Hiroto & Seligman, 1975). Furthermore, the helplessness effects of inescapable noise were greater for external locus of control individuals (Hiroto, 1974). Krantz, Gikass, and Snyder (1974) found similar results in two studies of inescapable versus escapable noise. One final detail of Hiroto and Seligman's work worthy of note is that the learned helplessness effects of inescapable noise were quite similar to the induction of helplessness produced by exposing subjects to insoluble concept formation problems.

A large number of studies, initiated by Glass and Singer's pioneering work on perceived control and stress (1972) have examined performance aftereffects, immediately following exposure to uncontrollable noise. The basic paradigm includes exposing participants to noise while working on a cognitive task for a period of about 30 minutes. The participant then leaves the room and is asked to do another, apparently unrelated task where noise is no longer present (see Cohen, 1980, for an overview of this paradigm). Uncontrollable noise causes deficits in task persistence on puzzles (Gardner, 1978; Glass & Singer, 1972; Glass, Singer, and Friedman, 1969; Percival & Loeb, 1980; Sherrod, Hage, Halpern, & Moore, 1977; Wohlwill, Nasar, DeJoy, & Foruzani, 1976). Work by Glass and Singer (1972) also showed that the controllability, and to a lesser extent the predictability, of the noise is a critical component of these aftereffects. In a test of the external validity of the initial Glass and Singer findings, Moran and Loeb (1977) utilized tape-recorded aircraft noise and found, unexpectedly, that such noise did not appear to induce aftereffects in the laboratory. Percival and Loeb (1980) reasoned that perhaps airport noise, because of its temporal qualities, is rather predictable. Thus, they replicated the original Moran and Loeb finding utilizing the same stimuli, but of particular interest, found that when the aircraft noise bursts were sudden rather than the typical slow onset pattern of an approaching aircraft, negative aftereffects could be reliably produced. Rotton, Olszewski, Charleton, and Soier (1978) also showed that meaningful speech rather than noise could induce the same negative aftereffect. Evans et al. (1996) indicated that these negative aftereffects are amplified if exposure to uncontrollable noise occurs among subjects already under psychological stress. Finally,

Glass and Singer (1972) found that uncontrollable noise interferes with subsequent proofreading accuracy.

A small number of studies has also examined possible relations between chronic noise exposure and susceptibility to helplessness. Evans et al. (1995) adapted the Glass and Singer aftereffects puzzle for young children. They found that children living in high airport noise zones were less likely to persist at solving line tracing puzzles than their quiet community counterparts. Cohen and colleagues (Cohen et al., 1980, 1981) found that aircraft noise-exposed children were significantly less likely to solve a difficult, challenging puzzle than quiet comparison groups. Of particular interest, noise-impacted children were also more likely to simply give up on the puzzle before the allotted 4 minutes had passed. Fifteen percent of children from noisy schools failed the puzzle by giving up in comparison to only 2% of children from quiet schools. It is worth noting that the puzzles were designed and pretested to be fun and engaging to elementary-aged schoolchildren. These effects were replicated by Cohen and colleagues and similar trends were also found for home noise levels (Cohen et al., 1986). Both the Evans and Cohen studies had well-matched SES comparison groups. Moch-Sibony (1984) found very similar results in kindergarten children exposed to higher levels of aircraft noise in Paris. Wachs (1987) also showed that infants exposed to more noise at home manifest less mastery-oriented play as indexed by a standardized observation instrument. Of additional interest, teachers in noisy schools frequently report more difficulties motivating students than do teachers from quiet schools (see Evans & Lepore, 1973b, for a review). Finally, Cohen et al. (1986) uncovered a relation between children's willingness to relinquish choice and chronic noise exposure. Children from noisy schools relative to quiet schools were significantly more likely to allow an experimenter to choose a reward at the conclusion of their experiments rather than make their own choice.

Summary

Both industrial and community studies find no clear, consistent pattern of data on noise and morbidity. Similarly, data on acute noise exposure and altered immune functions are mixed. Although not plentiful, there is a confluence of findings suggestive of noise impacts on in utero development that warrant followup. Several studies point to noise as a factor in elevated smoking.

Acute noise produces short-lived elevations in cardiovascular and neuroendocrine functioning. Recent research suggests, however, that individuals sensitive to noise as well as situations with high workload demands can diminish and perhaps even block such habituation. A plethora of methodologically weak, occupational noise and health studies reveal decidedly mixed findings on noise and blood pressure. Some longitudinal studies indicate small, positive associations between occupational noise exposure and blood pressure elevations. Road traffic noise appears to have no significant impact on blood pressure of community residents, but persons living in the proximity of airports, particularly children, are at risk

for elevated blood pressure. The clinical significance of these elevations is unknown at this time.

Data on noise and psychological health are unclear. The preponderance of poorly designed studies links community noise levels to rates of psychiatric illness. There are better studies indicating some link between community noise exposure and utilization of pharmaceutical hypnotics. Both laboratory and field studies reveal that noise, particularly uncontrollable noise, can contribute to diminished motivation related to learned helplessness. Children chronically exposed to noise may be particularly susceptible to this phenomenon.

DISCUSSION

Application of the construct of psychological stress to examine the role of the physical environment in human health has proven useful in the case of crowding and noise. The primary contributions to date have been the identification of stress-related outcome measures likely to be related to environmental stressors and the preliminary development of a conceptual model for thinking about how and under what conditions noise, crowding, and other environmental stressors might adversely impact human well-being.

Conceptual Issues

A central deficiency has been an inattention to the role of underlying psychophysiological processes or social resources in the environmental stressor-disease link. In searching for answers to the question, why does crowding or noise cause disease?, there are very little data that has tested mechanisms like elevated cardiovascular functioning or diminished self-efficacy. What the data generally show, as depicted in Fig. 20.2, is a broad set of outcome measures independently assessed.

More studies are needed that simultaneously investigate physical or psychological health outcomes and one or more underlying processes in the same sample of individuals. For example, Evans and Lepore (Evans et al., 1989; Evans & Lepore, 1993a; Lepore et al., 1991) showed evidence for the model shown in Fig. 20.3—namely, that high residential density causes deterioration in social support resources, which in turn accounts for the linkage between density and psychological ill health.

There are an unbelievably large number of studies of noise and cardiovascular functioning (principally blood pressure) that have not also looked at some disease endpoint. Similarly, no studies have examined crowding, immune function, and physical morbidity.

Several psychophysiological mechanisms are prime candidates for more in-depth scrutiny as intervening processes that could link environmental conditions to ill health. Alterations in neuroendocrine functioning affect cardiovascular activity, primarily via adrenomedullary action as well as alter immune functioning via adrenocortical pathways (Baum & Grunberg, 1995).

Cardiovascular reactivity is another process warranting analysis. Two viable, competing hypotheses exist. Sustained, chronic exposure to uncontrollable, environmental stressors

like crowding or noise may deplete the organism's ability to respond adequately to challenge with cardiovascular mobilization (Dienstbier, 1989). Alternatively, heightened sensitivity and vigilance from chronic stressor exposure might exacerbate reactivity (Krantz & Manuck, 1984).

Learned helplessness and other motivational processes related to chronic environmental stressor exposure have not been adequately developed. It seems clear that one of the potentially most injurious aspects of chronic environmental stressors is their intractability. Several aspects of motivation and chronic environmental stress warrant additional research. The role of attributional processes, which is well documented in the helplessness literature, has not been applied to environmental stress research. It is clear that attributional processes are salient to environmental stressors like noise and crowding. Noise annoyance is strongly affected by attributions about the origins of noise stimuli, as well as their perceived health impacts (Koelega, 1987). Feelings of arousal induced by personal space invasions (Worchel & Teddlie, 1976), expectancies (Schmidt & Keating, 1979), or informational cues (Langer & Saegert, 1977; Paulus & Matthews, 1980) can all be attributed to crowding or other environmental conditions with varying consequences. The potential interplay among environmental stressors and uncontrollability, helplessness, and negative health outcomes (such as depression) is an area ripe for further study. Motivation or effort to maintain task performance or productivity under suboptimal conditions may be a salient factor, as well, in determining the long-term health consequences of chronic exposure to adverse environmental conditions. Several noise studies both in the laboratory and the field, as well as one crowding study indicate that task performance can be sustained under adverse conditions but at a "cost" of psychophysiological activation. The long-term health consequences of people expending additional effort to do their job when the environment is not optimal is an important and unresearched topic.

Studies of underlying psychosocial processes, such as social support or control, also raise provocative conceptual issues about environment, stress, and coping. Social support and control have each traditionally been conceptualized as exogenous factors that moderate stressor-outcome relations. As can be seen herein, however, chronic exposure to crowding or to noise directly effects social support and control processes, respectively. These psychosocial processes mediate rather than moderate the impacts of these chronic environmental demands. Other chronic stressors may have similar effects on coping resources.

In considering hypothetical mechanisms, it is also prudent to carefully scrutinize the traditional practice of statistically controlling risk factors in environmental epidemiology. For example, several noise and coronary heart disease investigations control for smoking levels. However, what if noise exposure increases smoking as a coping device, as suggested by some studies already reviewed? By statistically partialling out a "risk" factor, a psychologically relevant process that may underlie the noise-health link has been eliminated.

At a more abstract level, the construct validity implications of statistical controls or the practice of random assign-

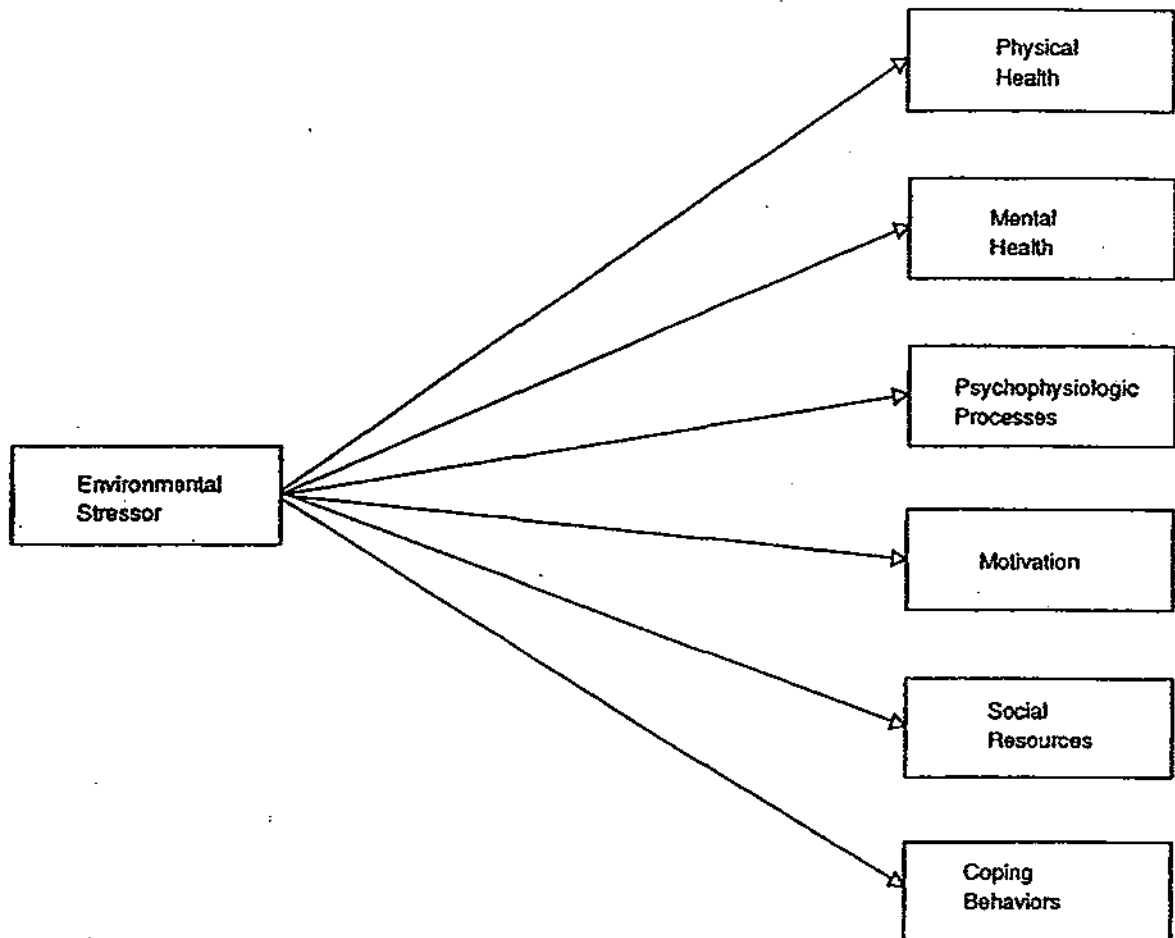

FIG. 20.2

FIG. 20.3

ment in experimental studies of stress and health should be carefully considered. By removing environmental stressors from their natural context (i.e., poverty, other suboptimal environmental factors) for the purposes of study, ecological validity of the stressor–health relation may be distorted. Perhaps crowding and poverty together or noise and certain job requirements together, respectively, lead to pathology. By isolating one independent variable either through statistical or experimental design means for purposes of causal modeling, the actual incidence of adverse outcomes from suboptimal en-

vironmental conditions may be dramatically underestimated (Lepore & Evans, 1996).

It might also be valuable to conceptualize the physical environment not only as a source of stress but also as a source of coping resources (Becker, 1990). Research on coping, like stress, tends to overly focus on intrapsychic mechanisms, missing the potential role of the social and physical environment to promote or interfere with health. For example, research on crowding suggests that floorplan layouts that incorporate greater intervening, hierarchically arranged

spaces, buffer the negative effects of residential crowding on psychological distress (Evans, Lepore, & Schroeder, 1996). Similarly, children in crowded homes who have a place where they can spend some time by themselves appear to suffer fewer negative outcomes (Wachs & Gruen, 1982).

Although children exposed to multiple risk factors are more likely to suffer adverse physical and mental health outcomes, some children are more resilient than others (Rutter, 1987). Bradley and colleagues (1994) found that low residential density was a significant, independent, protective factor among poor, low birth weight babies tested 1 and 3 years later on a wide array of physical and psychological health measures.

Methodological Issues

In addition to some of the conceptual issues associated with statistically controlling for risk factors, statistical approaches that partial out variables in order to "control" for possible confounding effects are also fraught with analytic problems. Statistical models that partial or covary out variables are based on the assumption of no interaction between the independent variable and the potential control variable on the outcome. Controlling for social class, for example, presupposes that noise or crowding do not interact with social class to affect health or well-being. The same statistical problem may occur with controls for certain risk factors, such as family history of coronary heart disease, hypertension status, or age, to name some common examples. Utilization of analysis of covariance or its regression equivalents assumes that the slopes of the respective regression lines between the outcome variable and the independent variable and the covariate (partial b) are parallel (i.e., no statistical interaction). Researchers should not employ covariance or analogous regression procedures to control for risk factors or contextual factors, such as socioeconomic status, without first assessing this basic statistical assumption.

Another analytic issue concerns effect size considerations. When the correlation coefficient between noise exposure and blood pressure, for example, is squared, not a lot of variance is explained. But this is also true if the same is done for cigarette smoking and lung cancer. It is also true that the variance explained in mental health by crowding is on the same order of magnitude as the variance explained by income (Evans et al., 1998; Gove & Hughes, 1983). Critics of the apparently small role of the physical environment in health need to grapple with this issue more in comparative, rather than in absolute, terms.

There is critical need for prospective, longitudinal designs in the field. There is only one crowding study incorporating such a design (Lepore et al., 1991) and just a handful of industrial studies of noise and health that incorporate a longitudinal component. Self-selection into noisy or crowded environments, as well as possible spuriousness, loom as major threats to internal validity in most of the field studies reviewed herein. Too many cross-sectional field studies exist. Furthermore, not enough integrated research programs have examined the same environmental stressor and health in the lab and in the field. The value of integrating lab and field work is illustrated by Cohen and colleagues' work on aircraft noise and

children where laboratory-based concepts and measures were brought to bear on the study of chronic, community noise exposure (Cohen et al., 1986).

Caution is needed in generalizing from aggregate level, epidemiological studies to individual health responses to the physical environment. Several examples of this ecological fallacy were previously reviewed, particularly in crowding field studies, where people per room as indexed by census tract did not yield the same pattern of results as when individual health measures were assessed. Parallel trends were noted in the noise and health literature (Lercher, 1996). One reason aggregate-level comparisons can be misleading is related to exposure estimation. Large degrees of variance in exposure are truncated into a single estimate of exposure when aggregate level data are examined. Furthermore, the actual environment as experienced is even further removed from the exposure metric in comparison to individual residential or work environment assessments.

The problems of exposure estimation and adequate representation of physical stressors in studies are common in the environmental stress literature. Many studies have only gross estimates of actual exposure to the physical stressor. Crowding and noise are typically estimated indirectly and do not account for individual movement throughout the day across settings. One indication of the importance of this issue is found in the noise literature where several studies on industrial noise show that duration of exposure is a critical variable. Similarly, utilization of hearing protection affects noises and health findings in industrial settings. Residential room location can also impact noise exposure (Lercher, 1996). An interesting example of the importance of exposure estimation comes from a recent study by Maxwell (1996) of crowding in preschoolchildren. Children in more crowded day-care centers had greater behavioral and emotional problems only if they also lived in crowded homes.

Moreover, the range of environmental variables in many studies is often truncated and/or the distribution of environmental exposures is badly skewed. Both of these problems strain the general linear model that forms the underlying statistical basis employed in most studies of the physical environment, stress, and health. For example, many studies of crowding have hardly any people in homes with more than 1.5 persons per room. Most laboratory studies expose people to quiet or noise and several community noise studies transform continuous data into a noise/quiet dichotomy. Badly skewed data, as well as use of dichotomous categories, reduce statistical power.

Furthermore, there is some indication of threshold effects for noise and crowding health effects. Recall for example some recent evidence that traffic noise above 65 dBA Leq appears necessary before cardiovascular risk elevates. This nonlinearity also adversely affects statistical power. Studies of traffic congestion and health outcomes indicate that log transformations (Halpern, 1995), or use of indices such as percentage of time at high congestion levels (Evans & Carrere, 1991), predict outcomes significantly better than do mean levels of exposure. This nonlinearity can also appear at the opposite end of the environmental exposure spectrum. Living alone is associ-

ated with psychological impairment as well as low social support (Gabe & Williams, 1987; Galle et al., 1972). Crowding studies that calculate persons per room as the density metric that include people living alone distort the estimate of association between crowding and health outcomes.

Outcome measures are also wanting. Several studies of psychological health employed one item or scales of unknown psychometric properties. Studies of health sorely need standardized, sensitive indicators. Immune function would be a particularly valuable adjunct to environmental morbidity studies. Several studies of blood pressure incorporated one or two readings, often taken in a medical setting. Such data are unreliable and of questionable validity.

Health psychology has demonstrated that individual, biological, and personal characteristics are central to understanding health and disease. A smaller body of work within health psychology has also examined the potential role of sociocultural factors in human health. Hopefully, this chapter has directed attention to the potential direct, indirect, and interactive roles the physical environment can play in health and human behavior.

ACKNOWLEDGMENTS

Preparation of this chapter was partially supported by grants from the National Institutes of Health (1 RO1 HL47325-01) the National Science Foundation (BNS-8920483) and the U.S. Department of Agriculture (Hatch-NY 327407). I am grateful to Jana Cooperman and Tamir Ebbin for bibliographic assistance. I thank Steve Lepore, Paul Paulus, and Shirley Thompson for critical feedback on earlier drafts.

Research Report

CHRONIC NOISE EXPOSURE AND PHYSIOLOGICAL RESPONSE: A PROSPECTIVE STUDY OF CHILDREN LIVING UNDER ENVIRONMENTAL STRESS

Gary W. Evans,¹ Monika Bullinger,² and Staffan Hygge³

¹Cornell University; ²Universitätskrankenhaus Eppendorf, Hamburg, Germany; and ³Kungl Tekniska Högskolan, Gävle, Sweden

Abstract—Chronic exposure to aircraft noise elevated psychophysiological stress (resting blood pressure and overnight epinephrine and norepinephrine) and depressed quality-of-life indicators over a 2-year period among 9- to 11-year-old children. Data collected before and after the inauguration of a major new international airport in noise-impacted and comparison communities show that noise significantly elevates stress among children at ambient levels far below those necessary to produce hearing damage.

People typically characterize environmental issues as physical health or technological problems. But the physical environment may also have adverse psychological impacts. Suboptimal environmental conditions, such as noise and crowding (Cohen, Evans, Stokols, & Krantz, 1986; Evans & Cohen, 1987), air pollution (Evans, 1994), or disasters (Baum & Fleming, 1993), may elicit psychological coping reactions, including cardiovascular and psychoneuroendocrine activation (Baum, Grunberg, & Singer, 1982; Frankenhaeuser, 1986; Lundberg, 1984). In the present article, we provide prospective, longitudinal evidence that chronic noise elevates psychophysical stress and depresses perceived quality of life.

Although noise can cause hearing deficits (Kryter, 1994), nonauditory, stress effects of noise have not been demonstrated definitively because of methodological and conceptual limitations in prior research. Laboratory studies indicate that acute noise elevates psychophysiological stress (e.g., blood pressure, epinephrine), but these responses habituate rapidly (Evans, in press; Glass & Singer, 1972; Hygge, 1997).

Psychophysiological stress responses to chronic noise have been investigated in industrial settings and in communities proximate to highways and airports. These cross-sectional studies, unfortunately, are subject to an array of plausible alternative explanations, particularly self-selection bias. Although suggestive trends linking occupational noise exposure and hypertension exist, the designs of these studies are so weak that definitive conclusions cannot be drawn (Evans, in press; Thompson, 1993). Poor or nonexistent control groups, nonrigorous assessments of blood pressure (e.g., one reading while on the job), and insufficient estimation of noise exposure plague industrial studies of noise and cardiovascular parameters.

Community studies of aircraft noise reveal elevated psychophysiological stress among children (Evans, Hygge, & Bullinger, 1995; Evans & Lepore, 1993). All of these studies are cross-sectional and, with one exception (Evans et al., 1995), limited to blood pressure. Knipschild (1977) has also shown a dose-response function between noise exposure in the community and hypertension among adults around the Amsterdam airport. The most clear-cut evidence that noise causes ele-

vated psychophysiological stress comes from a primate laboratory study (Peterson, Augenstein, Tanis, & Augenstein, 1981). Simulated air- and road-traffic noise produced stable, elevated arterial blood pressure over a several-week period in the laboratory.

Many noise studies have obscured not only methodological issues, but also important conceptual issues. First, with few exceptions, investigators have not screened for hearing damage. One cannot presently say with any confidence whether stress correlates of community and occupational noise exposure are mediated by hearing loss. Second, nearly all the field studies have confounded acute and chronic noise exposure. Typically, testing has occurred in situ. If individuals are not tested under quiet, carefully controlled conditions, one cannot confidently attribute stress responses to chronic versus acute noise exposure.

The present study took advantage of a natural experiment created by the opening of a new international airport located in a rural area 35 km outside of Munich, Germany. Resting blood pressure, overnight levels of neuroendocrine hormones, and quality of life were measured over a 2-year period among elementary school children residing in the flight paths of this airport before and after its inauguration. Comparison groups of sociodemographically well-matched children from nearby rural communities were also assessed over the same time period.

METHOD

Subjects

Participants were 217 third- and fourth-grade children (mean age = 9.90 years at the study's onset) living either proximate to the new Munich International Airport or in nearby communities outside the noise impact zone of the new facility. The total of 217 participants reflects attrition of 10 and 14 children, respectively, from the noisy and quiet areas. Attrition was unrelated to the outcome variables.

The measures of noise were 24-hr dBA Leq, an unweighted mean of energy level expressed in decibels, and dBA L01, the dBA level exceeded 1% of the time over the sampling period (24 hr in the present case). The dBA scale is logarithmic, and the human observer experiences an increase in 10 dBA as approximately a doubling of loudness. Following inauguration of the new airport, dBA Leq equaled 62, with a dBA L01 of 73, in the noise-impacted communities. Among the quiet communities at the same time period, dBA Leq was 55, with a dBA L01 of 64. Prior to the opening of the new airport, dBA Leq was 53, with a dBA L01 of 63, in the airport communities, and noise levels were comparably low in the comparison areas (dBA Leq = 53, dBA L01 = 64).

Children in the quiet comparison communities were matched to the children in the noise-impacted communities according to socioeconomic status. Households did not differ in the type of occupation, $\chi^2(4, N = 197) = 8.91$; parental education, $t(214) < 1.0$; or family size, $t(214) < 1.0$. All of the children in the study were screened for normal hearing with an audiometric examination.

Noise Exposure and Physiological Response

Procedure

Testing occurred in a sound-attenuated, climate-controlled mobile laboratory parked outside the child's elementary school. A microphone (6 m above ground) interfaced with a B&K Model 4426 Community Noise Level Analyzer monitored 24-hr outdoor noise levels at the trailer. Data were collected 6 months prior to the opening of the new airport (Wave 1), 6 months after the opening (Wave 2), and again 18 months after the opening (Wave 3), for a total of three assessment phases per participant.

Resting blood pressure was assessed with an automated monitor (A & D Digital, UA 751) while the child sat comfortably with his or her right arm supported at heart height on a table. Baseline readings were calculated by taking the average of six resting indices taken on 2 consecutive days. On each day, four readings were taken after an orientation to the automated monitor, and the first reading was discarded. Reliability estimates for the six readings exceeded an alpha of .85 for both diastolic and systolic blood pressure.

Twelve-hour overnight urine samples were collected between 20:00 on the evening of the initial testing day and 8:00 the following morning. The container was kept refrigerated and contained a preservative. Parents returned the urine specimen container the next day to the trailer. Total volume was measured, and small replicate samples of urine were extracted and deep frozen at -70°C until assayed. Half of the replicates were also pH adjusted to reduce oxidation further for the catecholamine assays. Epinephrine and norepinephrine were assayed by high-performance liquid chromatography with electrochemical detection (Riggin & Kissinger, 1977). Cortisol was determined by a radioimmuno assay (Baxter Travenol Diagnostics, Cambridge, Mass.). (For further information about procedures for the collection and assay of urinary neuroendocrine samples, see Baum & Grunberg, 1995, and Grunberg & Singer, 1990.)

Quality of life was assessed by the KINDL, a valid and reliable index of the principal domains of quality of life (physical, psychological, social, functional daily life; Bullinger, von Mackensen, & Kirchberger, 1994). These domains were combined for the present analysis ($\alpha = .92$).

RESULTS

The data analytic strategy was to conduct a 2×3 repeated measures multivariate analysis of variance (MANOVA). The principal statistic of interest is the exact F test for the interaction of group (noise impacted vs. quiet) and time (Wave 1 vs. Wave 2 vs. Wave 3).

As can be seen in Table 1, blood pressure increased in the noise-impacted communities after Wave 1, with the opening of the new airport; much smaller changes occurred among the quiet, comparison communities. The interaction of group and time was significant for systolic blood pressure, MANOVA exact $F(2, 214) = 4.50, p < .01$, and marginal for diastolic blood pressure, $F(2, 214) = 2.83, p < .06$.

The overnight urinary neuroendocrine results are shown in Table 1 as well. Consistent with the elevations in blood pressure, both epinephrine, $F(2, 200) = 36.86, p < .001$, and norepinephrine, $F(2, 200) = 22.31, p < .001$, increased sharply among children living in the flight paths of the new airport after it opened; smaller increases were seen over the same period among the children residing in quiet communities. Changes in urinary cortisol over time were not systematically related to noise conditions, $F(2, 200) = 1.73, n.s.$ Degrees of freedom vary because of missing data.

As indicated in Table 2, quality of life declined significantly in the noise-impacted communities 18 months after the opening of the new airport, but remained relatively stable in the quiet, comparison communities, $F(2, 202) = 3.07, p < .05$.

Table 1. Measures of psychophysiological stress in the noise-impacted and quiet communities

Measure and community	Wave		
	1	2	3
Systolic blood pressure (mm Hg)			
Noise	97.2 (11.6)	101.6 (9.9)	102.4 (10)
Quiet	100.8 (8.9)	102.2 (8.9)	102.6 (12)
Diastolic blood pressure (mm Hg)			
Noise	60.5 (7)	63.2 (6.1)	64.4 (6.2)
Quiet	62.6 (7.1)	63.6 (6.4)	64.8 (6.8)
Epinephrine (ng/hr)			
Noise	229.2 (153.4)	328.1 (130.4)	341.9 (168.1)
Quiet	251.8 (57)	280.9 (64.6)	246.2 (83.7)
Norepinephrine (ng/hr)			
Noise	610.7 (338.6)	1,228.5 (659.7)	1,556.3 (703.6)
Quiet	660.0 (506.9)	879.7 (457.7)	950.7 (525.5)
Cortisol ($\mu\text{g/hr}$)			
Noise	3.56 (1.89)	4.36 (5.39)	5.14 (6.89)
Quiet	3.31 (1.89)	2.37 (6.14)	3.78 (2.89)

Note. The data shown are means, with standard deviations in parentheses.

Table 2. Quality of life in the noise-impacted and quiet communities

Community	Wave		
	1	2	3
Noise	110.3 (13.8)	112.4 (13.9)	104.8 (16.0)
Quiet	112.5 (16.4)	112.1 (17.0)	109.6 (15.5)

Note. The scale for the quality-of-life measure ranges from 40 to 200, with greater values indicating higher perceived quality of life. The data shown are means, with standard deviations in parentheses.

DISCUSSION

Chronic exposure to ambient aircraft noise elevates psychological stress in human beings. Children living proximate to the new Munich International Airport experienced significant elevations in resting blood pressure after the airport opened. During this same time period, well-matched children in nearby, similar communities experienced stable levels of resting blood pressure. The catecholamine data, which are consistent with the blood pressure effects, underscore the value of conceptualizing noise and other suboptimal environmental conditions as stressors. Elevated urinary catecholamines have consistently been shown to reliably and sensitively mark chronic exposure to stressors (Baum et al., 1982; Frankenhaeuser, 1986; Lundberg, 1984). Urinary cortisol has proven less reliable as an index of chronic stress exposure (Frankenhaeuser, 1986; Lundberg, 1984).

The self-report data show the same pattern, but with a delayed time course. Childrens' perceived quality of life dropped more markedly in the noise-impacted communities than in the quiet communities, but this drop did not occur until 18 months after the new airport opened.

As in any field study, some questions remain. We cannot disentangle the apparent effects of chronic noise from the uncontrollability of that exposure. Although the primary environmental change near the new airport was dramatic increases in sound levels, the surrounding community also witnessed increased land development, more road traffic, and the like.

Our prospective data add evidence to previous cross-sectional results that have shown elevated stress among adults and children working and residing, respectively, in chronically noisy environments. In young children, chronic noise exposure appears to cause increased psychological stress, as measured by cardiovascular, neuroendocrine, and affective indicators. These effects occur among children who suffer no detectable hearing damage while living in the immediate vicinity of an airport.

Acknowledgments—We are grateful to the families who cooperated with this research. We thank Sylvia von Mackensen, Markus Meis, Gerhard Helm, Gunnar Söderqvist, Christian Wigren, Nils Antoni, and Pat O'Keefe for their dedication to this project. This research was partially supported by the Society for the Psychological Study of Social Issues, the National Institutes of Health (R01 HL 4732 01A), the Nordic Scientific Group for Noise Effects, the Swedish Environmental Protection Agency, and the German Research Foundation. The second author was also supported by the DFG Heisenberg Fellowship.

Proposed chRDs for School Site Risk Assessment

Executive Summary

As mandated by Part 2 of the Health and Safety Code, section 901(g), the Office of Environmental Health Hazard Assessment (OEHHA) reviewed five chemicals to consider the development of child-specific reference doses (chRDs). This report summarizes OEHHA's review of pertinent scientific studies in proposing these chRDs. Any chRDs established as a result are intended for use in the risk assessment of proposed or existing California school sites.

OEHHA completed Part 1 of that mandate, which called for the identification of chemical contaminants commonly found at school sites and determined to be of greatest concern to children. The report, "Development of Health Criteria for School Site Risk Assessment Pursuant to Health and Safety Code, Section 901(g): Identification of Potential Chemical Contaminants of Concern at California School Sites," was posted on OEHHA's website in June, 2002. In summary, OEHHA identified seventy-eight chemicals that will likely be found as contaminants of California school sites and have the potential for causing adverse effects in children. This should be viewed as a living compilation – chemicals may be added or removed as new information becomes available.

OEHHA chose five chemicals from the compilation for an in-depth evaluation of non-carcinogenic effects: cadmium, chlordane, heptachlor and its metabolite heptachlor epoxide, methoxychlor, and nickel. The criteria used to select these chemicals for the first round of reviews are discussed in Chapter 1.

In reviewing the applicable scientific literature, OEHHA identified relevant quantitative studies from which to propose a chRD for each chemical. The chRD for the non-carcinogenic effects of cadmium is based on a 1999 study by Buchet et al. The authors reported a strong relationship between cadmium body burden and renal tubular dysfunction in adult humans. This study identified a lowest observed adverse effect level (LOAEL) of 1×10^{-3} mg/kg-day. From this LOAEL, OEHHA calculated a chRD of 1×10^{-5} mg/kg-day using an uncertainty factor of 30 (10 to account for human variability and 3 to extrapolate from the LOAEL to the no observed adverse effect level (NOAEL). A factor of 3 (rather than the usual default of 10) was used for extrapolating from a LOAEL to a NOAEL because the LOAEL was based on the minimal adverse effect observed. A child protective modifying factor of 3 was used to account for the child/adult difference in gastrointestinal absorption of cadmium for a combined uncertainty and modifying factors of 90.

The chRD for the non-carcinogenic effects of chlordane is based on a 1994 study by Cassidy et al. The authors demonstrated changes in sex-steroid mediated behaviors, including increased male-typical spatial abilities in female rats and increased male-typical mating behaviors in male rats, following pre- and postnatal exposure. This study identified a LOAEL of 0.1 mg/kg-day, from which OEHHA calculated a chRD of 3.33×10^{-5} mg/kg-day using an uncertainty factor of 3000 (10 for interspecies variability, 10 for human variability, 10 to extrapolate to the LOAEL from the NOAEL, and a modifying factor of 3 to account for an inadequate hematotoxicity/immunotoxicity and neurotoxicity database—toxicities to which children may be particularly sensitive).

The chRD for the non-carcinogenic effects of heptachlor is based on two studies. One is a 2001 study by Moser et al., which shows decreased performance on measures of cognitive function in male rats following pre- and postnatal exposure, through postnatal day 21. The other is a 2001 study by Smialowicz et al., which shows suppression of the primary IgM and secondary IgG antibody responses following exposure during the last half of gestation through puberty. Both studies identified a LOAEL of 0.03 mg/kg-day. OEHHA calculated a chRD of 3×10^{-5} mg/kg-day using an uncertainty factor of 1000 (10 each for interspecies variability, human variability, and extrapolation from LOAEL to NOAEL). The chRD for the non-carcinogenic effects of heptachlor epoxide utilizes the same study selected by U.S. EPA for its reference dose (RfD) and OEHHA for its Public Health Goal (PHG.) A LOAEL of 0.0125 mg/kg-day for liver-to-body weight ratio was reported when adolescent dogs were fed heptachlor epoxide for 60 weeks (Dow Chemical Co., 1958). Since exposure was to adolescent animals, OEHHA utilized the U.S. EPA RfD for its chRD of 1.3×10^{-5} mg/kg-day and utilized the same uncertainty factor of 1000 (10 each for interspecies variability, human variability, and extrapolation from LOAEL to NOAEL).

The chRD for the non-carcinogenic effects of methoxychlor is based on two studies as well. One is a 1995 study by vom Saal et al., which demonstrates increased urine marking in male mice, an index of territorial behavior, subsequent to prenatal exposure. The other is a 1999 study by Welshons et al., which shows an increase in adult prostate size following prenatal exposure. The LOAEL identified from these studies is 0.02 mg/kg-day. OEHHA calculated a chRD of 2×10^{-5} mg/kg-day using an uncertainty factor of 1000 (10 each for interspecies variability, human variability, and extrapolation from LOAEL to NOAEL).

The chRD for the non-carcinogenic effects of nickel is based on the observed pup mortality in three reproductive studies – Smith et al., 1993, and Springborn Laboratories, 2000 a and b. In reviewing these three studies in totality, OEHHA concludes that the 1.1 mg nickel/kg-day (5 mg nickel sulfate hexahydrate/kg-day) dose constitutes the appropriate NOAEL. From this NOAEL, OEHHA calculated a chRD of 3.7×10^{-3} mg/kg-day, using an uncertainty factor of 300: 10 each for interspecies extrapolation and human variability) and a child protective modifying factor of 3 to account for the child/adult difference in gastrointestinal absorption of nickel.

Table ES 1 below compares the chRDs and U.S. EPA's RfD, which are based on studies in adult animals.

Table ES 1 OEHHA's chRD and U.S. EPA's RfD

	OEHHA's Proposed chRD (mg/kg-day)	U.S. EPA's RfD (mg/kg-day)
Cadmium	1×10^{-5}	5×10^{-4}
Chlordane	3.3×10^{-5}	5×10^{-4}
Heptachlor	3×10^{-5}	5×10^{-4}
Heptachlor epoxide	1.3×10^{-5}	1.3×10^{-5}
Methoxychlor	2×10^{-5}	5×10^{-3}
Nickel	3.7×10^{-3}	2×10^{-2}

These proposed chRDs were reviewed internally. OEHHA is currently releasing this draft report for external peer review and public comment. Any chRDs established by this process are intended for use in risk assessment of proposed or existing school sites in California.

1. Introduction

This report summarizes the first-year effort of the Office of Environmental Health Hazard Assessment (OEHHA) in developing health criteria for five selected chemicals for use in school-site risk assessment. The following provides the context for this effort.

1.1 Mandate

As part of a series of legislative provisions in California to protect children from exposure to environmental contaminants, OEHHA has been tasked under Health and Safety Code, Section 901(g), to fulfill the following directives:

1. On or before January 1, 2002, OEHHA, in consultation with the appropriate entities within the California Environmental Protection Agency (Cal/EPA), shall identify those chemical contaminants commonly found at school sites and determined by OEHHA to be of greatest concern based on criteria that identify child-specific exposure and child-specific physiological sensitivities.
2. On or before December 31, 2002, and annually thereafter, OEHHA shall publish and make available to the public and other state and local environmental and public health agencies and school districts, numerical health guidance values for five of those chemical contaminants identified until the contaminants identified have been exhausted.

1.2 Identification of Chemicals

The first part of the mandate, identifying those chemical contaminants commonly found at school sites and determined to be of greatest concern based on criteria that identify child-specific exposures and physiological sensitivities, was completed earlier. Available data did not permit us to definitively identify those chemicals that are commonly found at school sites and for which children have unique physiological sensitivities. However, we have identified a group of candidate chemicals that will likely be found as contaminants at school sites (200 chemicals), and another group where evaluation of review literature provided some indication the chemicals may have the potential for causing adverse effects on school-age children (198 chemicals). The methods used to implement the first part of the mandate are summarized below; a detailed description can be found in the OEHHA June 2002 report, "Development of Health Criteria for School Site Risk Assessment Pursuant to Health and Safety Code, Section 901(g): Identification of Potential Chemical Contaminants of Concern at California School Sites," which can be downloaded at:

http://www.oehha.ca.gov/public_info/public/kids/pdf/ChildHealthreport60702.pdf.

In identifying contaminants likely to be found at California school sites, OEHHA considered chemicals that have been targeted by federal and state agencies as being pervasive in pertinent environmental media, in addition to contaminants that have been found at school sites or were on the list of analytes for monitoring studies at California school sites. Using these criteria, OEHHA considered the following as candidate contaminants that are likely to be found at school sites:

- Ninety-four soil contaminants that have been reported in school site Preliminary Endangerment Assessments (PEA) and reviewed by the Department of Toxic Substances Control (DTSC).
- Ninety Toxic Air Contaminants that were emitted to, or detected in, California's ambient air.
- Sixty potential classroom contaminants targeted for monitoring by the Department of Health Services (DHS) and the Air Resources Board (ARB), as part of their Portable Classroom Program.
- Forty-seven toxic chemicals targeted by U.S. EPA in its National Human Exposure Assessment Survey (NHEXAS).
- Twenty-six contaminants targeted by U.S. EPA in its Total Exposure Assessment Methodology (TEAM) studies.

Because of overlap among the chemicals reported or targeted by the above federal and state agencies, the final compilation consists of 200 chemical contaminants likely to be found at school sites.

In identifying chemicals with potential child-specific sensitivities, OEHHA considered the following:

- Chemicals with one or more citations in review articles from the scientific literature indicating the potential for adverse effects on the development of the nervous, respiratory, reproductive, endocrine, or immune system.
- Chemicals that initiated cancer following exposure during the perinatal period or childhood.
- Chemicals identified as Proposition 65 Developmental and Reproductive Toxicants by OEHHA, excluding chemicals not likely to be found at school sites, such as pharmaceuticals. While Prop 65 deals with chemical exposures that occur during pregnancy, the inclusion of these Prop 65 chemicals are useful for screening chemicals that may also impact developing organ systems postnatally.

The final compilation consists of 198 chemicals to which children are potentially more sensitive, 87 of which are from the Proposition 65 list.

To aid in implementing the second part of the mandate, the two compilations were merged into one comprehensive list of 78 chemicals that met both criteria. This list is given in table ES 1 in OEHHA's June 2002 report (page 5) and will be updated as new data become available. The information obtained to produce this compilation is not

sufficient to conclude that the compiled chemicals are found in most schools or that children have a greater sensitivity compared to adults. The compilation has been prepared to assist OEHHA scientists in selecting chemicals for further in-depth review to determine if sufficient studies on toxicity to developing organ systems in the young exist to create a health guidance value specific for children. The list has no regulatory status.

1.3 Numerical Health Guidance Values

The second part of the mandate, which is the subject of this report, requires OEHHA to annually publish numerical health guidance values for five of those chemical contaminants identified in the June 2002 report until the contaminants identified have been exhausted. In order to prioritize chemicals from the compilations generated in Phase I for in-depth review, OEHHA outlined the following criteria, which was also described in the June 2002 report, for selecting chemicals for in-depth reviews. It should be emphasized that these four criteria are not permanent, but are being used to help us prioritize which chemicals to evaluate first. The compilation of chemicals will continue to be updated and reviewed.

1. Chemicals having a strong indication of their presence at school sites according to monitoring studies or other reliable sources.
2. Chemicals cited to have possible adverse effects in three or more of the systems that are undergoing critical development during childhood: the neurological, immunological, respiratory, reproductive, or endocrine systems.
3. Where applicable, chemical carcinogens with existing reference toxicity levels based on studies in adult animals that approximate the dose associated with a 10^{-4} (one in ten thousand) to 10^{-6} (one in a million) lifetime cancer risk.
4. Chemicals that other OEHHA programs have identified as a public health concern based on studies pertinent to children.

The first criterion addresses the possibility that children will be exposed to a given chemical while at school, since a chemical must have some probability of being found at a school site in order to warrant consideration under this mandate. The compilation of chemicals potentially found at school sites (OEHHA, 2002) was used to gauge the likelihood of a chemical being present at California school sites.

The second criterion helps select those chemicals that appear to have multiple effects on organ systems that are still undergoing development and maturation after birth. The nervous, immune, respiratory, reproductive and endocrine systems are being targeted because chemical insults at relatively low doses to any of these organ systems could

produce adverse effects, many of which may not be recognized until maturity (OEHHA, 2002).

In focusing on these critical organ effects, we have targeted non-cancer endpoints. In a separate task, OEHHA is developing a cancer evaluation methodology for children pursuant to HSC Section 901(e). Because that methodology will not be available until 2004, we are focusing on identifying and evaluating the non-cancer effects of chemicals. We will assess the cancer endpoint when the children's cancer methodology is developed.

The criteria for selecting chemicals identified in review articles as having effects on multiple developing organ systems was intended to increase the probability of identifying relevant literature during the in-depth search and review phase. Targeting chemicals with evidence of effects in three or more systems may miss an important developmental toxicant for which either only one system is affected or only one system has been adequately researched. However, given time and budget constraints, we felt this was an effective way to prioritize the chemicals on the list this year.

The third criterion helps target those chemicals that could conceivably be non-cancer risk drivers when new child-specific data were considered. If current data suggest that both carcinogenic and non-carcinogenic effects of concern occur at similar dose levels in adults, and studies on developing organ systems show that exposure may produce irreversible non-carcinogenic effects in children at dosages lower than those that are toxic to adults, then the chemical should have a high priority for further evaluation.

The fourth criterion allows us to build on related work done by other OEHHA programs. This year we utilized the peer-reviewed PHGs for drinking water contaminants developed by OEHHA. More information on the PHG process can be found at the web address <http://www.oehha.ca.gov/water/phg/allphgs.html>. The PHG effort provides an excellent springboard from which to conduct our current review for developing child-specific chRDs because the Pesticide and Environmental Toxicology Section's (PETS') reviews are recent and they cover the chemicals of interest.

Using the above criteria OEHHA selected cadmium, chlordane, heptachlor and its metabolite heptachlor epoxide, methoxychlor, and nickel as the first five chemicals for in depth review. Under contract with OEHHA, the Public Health Library at the University of California at Berkeley searched the following databases: PubMed, Toxline/DART, Excerpta Medicus (EMBASE), Chemical Abstracts, BIOSIS, International Pharmaceutical Abstracts (IPA), and ISI Web of Science. We searched by keywords that describe specific effects on developing organ systems. The keywords used in searching these databases are listed in Appendix A.

OEHHA evaluated the citations returned by the literature search (105 citations for cadmium, 65 for chlordane and heptachlor/heptachlor epoxide combined, 82 for methoxychlor, and 18 for nickel), and reviewed relevant qualitative background papers and quantitative studies. In addition, OEHHA reviewed pertinent studies cited in papers

obtained via the literature search. Because so few citations were returned for nickel, an alternate, very inclusive approach (discussed in Section 2.5) was used to ensure that we were not missing important studies.

1.4 Child-Specific Reference Dose (chRD)

U.S. EPA and the March of Dimes sponsored a workshop -- Identifying Critical Windows of Exposure for Children's Health -- in September 1999 to systematically review the state of knowledge on prenatal and postnatal exposures and subsequent outcomes (Environmental Health Perspectives Volume 108, Supplement 3, June 2000). In reviewing data on organ systems that are still undergoing development and maturation in children, workshop participants noted that data pertaining to children's sensitivities to environmental contaminants during various critical developmental periods are limited. In particular, very little attention has been given to peripubertal/adolescent exposures or adult consequences from childhood exposure. However, these limited data do suggest that children could be more sensitive than adults when their developing organ systems were exposed to harmful chemicals. For example, several developmental immunotoxicants (chlordane, dioxin, lead, and benzo[a]pyrene) demonstrate that perinatal exposures can produce toxicity at doses that do not affect adults and/or they produce irreversible changes which do not occur with adult exposure.

Endocrine disruptors, a group of chemicals that may produce differential toxicity to the young, have been the subject of much recent scientific and regulatory debate (Cranmer et al., 1984; Colborn et al., 1993; U.S. EPA, 1998). While not all chemicals reviewed in this first year are endocrine disruptors, the endocrine disruptors do pose a great concern because they could interfere with the proper hormonal signaling that is essential for growth and development of school children. An endocrine disruptor may be defined as an exogenous agent that interferes with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body (U.S. EPA, 1997). Exposure to endocrine disruptors during critical "programming" periods in development, in contrast to exposure during adulthood, may produce irreversible effects on the reproductive, nervous, and/or immune system (Bigsby, 1999). In adulthood, these endocrine disruptors might only produce reversible effects by participating in the "seesaw" process of stimulation and feedback inhibition.

The effects of endocrine disruptors are more difficult to evaluate than chemicals which have a direct toxic effect on an organ system. Endocrine disruptors can act directly on hormone receptors of developing target organs, or they can act indirectly by interfering with the synthesis or metabolism of natural hormones. An endocrine disruptor having a direct interaction with either intracellular receptors or membrane-bound receptors can mimic a natural ligand by acting as an agonist, or if it inhibits binding, as an antagonist. The best known examples are methoxychlor, chlordecone (Kepone), DDT, some PCBs, and alkylphenols (Mueller and Kim, 1978; White et al., 1994; U.S. EPA, 1997). The antiandrogenic action of vinclozolin is the result of the affinity of its metabolites for the

androgen receptor (van Ravenzwaay, 1992; Kelce et al., 1994). O,p-DDT and chlordecone inhibit binding to both estrogen and progesterone receptors (Laws, 2000).

An endocrine disruptor can have an indirect effect on a target organ if it changes the quantity of a hormone or the ratio of several hormones at target organs by altering hormonal storage and/or release, transport in the blood and clearance, or post-receptor activation. Many different mechanisms can produce these changes.

Disruption of normal signaling, whether it causes a direct effect on a target organ, or whether it alters hormone ratios or levels, can produce an adverse effect on a single organ system -- the reproductive, immune or nervous system -- if the disruption occurs during a critical period in development (Kavlock et al., 1996). Disruption of normal signaling can also produce adverse effects on multiple organ systems. For example, estrogen receptors can be found in the gonads, thymus, and brain; and the disruption of estrogen signaling could simultaneously affect the reproductive, immune, and nervous systems (Colborn et al., 1993; Diel, 2002). To complicate the matter further, one endocrine axis can impact another in a "cross-talk" (WHO, 2002). For example, in humans and some other mammals, most of the testosterone and estradiol circulating in the bloodstream are not bioavailable because of their binding to sex hormone binding globulins (SHBG). Not surprisingly, SHBG production is regulated by testosterone and estradiol (Prinsloo and Van Aswegen, 2000; Pugeat et al., 1996). However, via cross-talk, SHBG is also regulated by insulin. Thus, an insulin disruptor that causes an elevated insulin level would suppress SHBG production, leading to an increase in testosterone and estradiol bioavailability (Pugeat et al., 1996).

Given the complexity of hormonal signaling processes, it is also not surprising to find the relationship between dose and response to be another controversial issue. Endocrine disruptors often act by mimicking or antagonizing the actions of naturally occurring hormones that may be already at physiologically functional concentrations (WHO, 2002). The National Toxicology Program's Report of the Endocrine Disruptors Low Dose Peer Review concluded that biological changes occurred in the range of human exposures or at doses that are lower than those typically used in the EPA's standard testing paradigm for evaluating reproductive and developmental toxicity for endocrine active agents (<http://ntp-server.niehs.nih.gov/htdocs/liason/LowDosePeerFinalrpt.pdf>). Too little is known about the dose-response curves for immunotoxicity, neurotoxicity, or endocrine effects to decipher the independent or interactive effects of endocrine disruptors on these systems. The shape of the dose response curve varies with the endpoint and dosing regimen and it may be low-dose linear, threshold-appearing, or it may be shaped like an upright U or an inverted U (<http://ntp-server.niehs.nih.gov/htdocs/liason/LowDosePeerFinalrpt.pdf>; Markowski et al., 2001; vom Saal et al., 1997).

The above observations underscore some of OEHHA's challenges in implementing HSC Section 901(g) pertaining to the development of health criteria based on children's sensitivities. As discussed by Ginsberg et al. (2002) and Miller et al. (2002), the risks

that children incur from exposure to environmental contaminants could differ from adult risks as a result of the following factors:

- Greater exposure in young children from a higher inhalation and food ingestion rate per body weight; and greater contact with soil, house dust and other media that may contain contaminants.
- Pharmacokinetics differences between children and adults with respect to absorption, metabolism, clearance, protein binding, and volume of distribution, once exposure has occurred.
- Pharmacodynamic differences between children and adults; that is, the sensitivity of rapidly developing tissues/organs in children may differ from that in adults.

The exposure differences will be addressed under a separate task -- developing the school exposure assessment guidelines -- pursuant to HSC Section 901(f). Based on available pharmacokinetic and pharmacodynamic data, we will evaluate if existing U.S. EPA RfDs or OEHHA toxicity criteria are appropriate, or if child-specific ones should be proposed, for school-site risk assessment in California.

From a public health protection standpoint, OEHHA has adopted two policies in developing chRDs. First, in order to protect children from conception through the time they leave school, chRDs must consider school-aged children up to age 18; and infants and toddlers in daycare facilities located at school sites. Second, OEHHA opts to consider the most sensitive species and endpoints in our evaluations, meaning that the lowest LOAEL or NOAEL from available literature would be selected. Moreover, the paucity of data has underscored the reality that the databases for sensitive endpoints may be incomplete. An uncertainty factor for database deficiency will be considered as appropriate.

Our mandate, which is driven by environmental health policies, has charted OEHHA's course of action. We view this approach as an iterative process. Any chRD established will be subject to review and refinement as the state-of-the-science progresses.

2. Evaluation of Five Chemicals

This chapter is divided into five sections, one for each chemical reviewed in 2002. Each section provides information specific to the particular chemical, including background and exposure information; how the chemical meets our criteria for evaluation; existing pertinent health guidance values; findings from our literature review; and OEHHA's recommendation. The recommendation includes a discussion of the study (or studies) used in developing the chRD, the uncertainty and modifying factors used, the calculation, and the proposed chRD.

2.1 Cadmium

Cadmium is an important industrial chemical with diverse applications. It is used for the production of nickel-cadmium batteries, pigments, alloys, plastics, and synthetics. It is also used in metal plating. The Toxic Chemical Release Inventory of 2000 shows that 2,292 pounds of cadmium were emitted into the air, 792 pounds were discharged into surface water, 69,000 pounds were injected underground, and 663,895 pounds were released to land in the U.S. In comparison, 16 pounds of cadmium entered the air and 36,104 pounds were disposed of on land in California during 2000 (U.S. EPA, TRI2000).

Given its indestructible nature, cadmium persists in the environment, and can enter the food chain. OEHHA identified air, drinking water, soil, and food as the primary pathways for human exposure to cadmium (OEHHA, 1999a). U.S. EPA and ARB/DHS have deemed cadmium as a chemical of interest in their NHEXAS and Portable Classroom Study, respectively (OEHHA, 2002). ARB reported the occurrence of cadmium in California air and DTSC reported the presence of cadmium at 10 percent of the potential school sites reviewed by the Department, making it a relatively frequently observed contaminant.

In reviewing literature for the purpose of establishing a Public Health Goal (PHG) for cadmium in drinking water (OEHHA, 1999a), OEHHA found some evidence that cadmium may elevate blood pressure in both animals and humans. Renal toxicity of cadmium is well known. Cadmium tested positive in several mutagenic assays and in an epidemiological study; it was observed that individuals with higher levels of cadmium in their urine ($>3 \mu\text{g/L}$) had more frequent chromosomal aberrations in their lymphocytes. A number of studies in rats and mice indicated the developmental and reproductive toxicity of cadmium. Neurological and immune effects were also reported. Finally, tumors of the prostate, testes and hematopoietic system in the rat were associated with oral cadmium exposure; and human lung and prostate cancers had been associated with inhalation exposure. Thus, it is regarded as a potential human carcinogen by the oral route and a human carcinogen by the inhalation route.

OEHHA selected cadmium for an in-depth review in this first cycle not only from the standpoint of its exposure potential at school sites, but also because of its adverse effects

on various organ systems; some of which are still undergoing development in school children.

Pertinent Guidance Values

U.S. EPA RfD: 0.5 µg/kg-day (water) and 1.0 µg/kg-day (food)

U.S. EPA's RfD is based on cadmium's effect on the kidney. A concentration of 200 µg cadmium (Cd)/g wet human renal cortex is the highest renal level not associated with significant proteinuria (U.S. EPA, 1985). A toxicokinetic model is available to determine the level of chronic human oral exposure (NOAEL) which results in 200 µg Cd/g wet human renal cortex; the model assumes that 0.01 percent day of the Cd body burden is eliminated per day (U.S. EPA, 1985). Assuming 2.5 percent absorption of Cd from food or 5 percent from water, the toxicokinetic model predicts that the NOAEL for chronic Cd exposure is 0.005 and 0.01 mg Cd/kg-day from water and food, respectively (i.e., levels which would result in 200 µg Cd/g wet weight human renal cortex). Thus, based on an estimated NOAEL of 0.005 mg Cd/kg-day for Cd in drinking water and an uncertainty factor (UF) of 10 that accounts for intra-human variability, an RfD of 0.0005 mg Cd/kg-day (water) was calculated; an equivalent RfD for Cd in food is 0.001 mg Cd/kg-day.

U.S. EPA gives a high confidence to its cadmium RfD. The choice of NOAEL does not reflect the information from any single study. Rather, it reflects the data obtained from many studies on the toxicity of cadmium in both humans and laboratory animals. These data also permit calculation of pharmacokinetic parameters of cadmium absorption, distribution, metabolism and elimination.

OEHHA PHG: 0.07 µg/L (a safe dose of 1×10^{-5} mg/kg-day)

OEHHA deemed the Buchet investigation (Buchet et al., 1990) as the best study for use in developing a Public Health Goal (PHG) for cadmium in drinking water. The study avoided the healthy worker effect by performing a cross-sectional examination on 1699 Belgian subjects between the ages of 20 and 80 years. The investigators found a strong relationship between cadmium body burden and renal tubular dysfunction. They observed a risk of renal effects at or above the urinary excretion rate of 2 µg cadmium/24 hours. Assuming an oral absorption rate of 5 percent and a daily excretion rate of 0.005 percent of body burden, Buchet estimated that this excretion rate corresponded to a mean renal cortex concentration of about 50 ppm or 50 µg/g (wet weight). In non-smokers (investigators' design to subtract a major source of cadmium from tobacco smoke), this level is reached after 50 years of an oral daily intake of 1.0 µg/kg body weight. As such, a LOAEL of 1.0 µg/kg-day was established.

OEHHA (1999a) applied this LOAEL in conjunction with an aggregated uncertainty factor (UF) of 100 (10 for intra-human variability, 3 for LOAEL to NOAEL extrapolation, and 3 for uncertainty in applying adult biokinetics to the entire age range from infancy to adulthood) for calculating a safe dose of 0.01 µg/kg-day. A factor of 3

(rather than the usual default of 10) was used for extrapolating from a LOAEL to a NOAEL because the LOAEL was based on the minimal adverse effect observed. The safe dose in turn was used to derive the PHG.

Current Evaluation Results

Because the cadmium data have recently been reviewed under the PHG process, we used the PHG review as a baseline for the current evaluation. Accordingly, we focused our literature search and review on the information that was not covered by the PHG evaluation. An attempt was also made to target literature pertaining to cadmium's effect on sensitive organ systems that are still undergoing postnatal development.

Based on the above search criteria, we compiled a list of references. From that list, we identified a number of papers relevant to cadmium's effects on testes and semen of rabbits exposed before and after puberty (Foote, 1999); pubertal and postpubertal cadmium exposure on the hypothalamic-pituitary-testicular axis function in rat (Lafuente et al., 2000); cadmium induction of apoptosis in the immune system (Tsangaris et al., 1998); postnatal cadmium exposure and long-term behavioral changes in rat (Smith et al., 1982); effects of cadmium and lead on cognitive functioning in children (Thatcher et al., 1982); and neurotoxic effects of cadmium in young rats (Wong et al., 1982). However, these were either qualitative/mechanistic, semi-quantitative, or quantitative studies with a LOAEL higher than that on which the PHG was based.

Recommendation

The renal effect of cadmium seems to be the most sensitive endpoint (with the lowest LOAEL), even when it is compared with developmental and reproductive study endpoints identified in the OEHHA PHG document or those identified by OEHHA's current evaluation. The rate of cadmium absorption affects its rate of accumulation in the kidney, and in turn its toxicity. Thus, available data suggest the PHG LOAEL should be retained for our current consideration. This LOAEL is lower than the NOAEL used by U.S. EPA in developing its RfD. Both the safe dose from which the PHG was derived and U.S. EPA's RfD are based on cadmium's effect on renal function. In developing these two health criteria, long-term cumulative exposure data were used. Both U.S. EPA and Buchet et al. applied a 5 percent absorption in their respective biokinetic modeling, based on adult human absorption of 4.7 to 7 percent of the cadmium intake (Rahola et al., 1972, cited in Mahaffey, 1983). In proposing the PHG, OEHHA applied a factor of 3 to account for the uncertainty associated with Buchet's modeling in which he applied adult biokinetics to the entire age range from infancy to adulthood. According to Alexander et al. (1974), the absorption of cadmium by children, from early infancy through 8 years of age, averages 55 percent.

To illustrate the appropriateness for applying the factor of three for developing the chRD, OEHHA ran a model similar to Buchet, using his modeling assumptions. Using a daily dose of 1 µg/kg, an absorption rate of 5 percent, and a daily clearance rate of 0.005

percent of body burden, OEHHA estimated that the urine excretion of 2 µg cadmium /24 hour (LOAEL biomarker) would be reached by age 53, which was in good agreement with Buchet's study. However, by changing the absorption rate to 55 percent through age 8, then decreasing it linearly to 5 percent at age 21, while keeping the other parameters the same, a daily dose of 0.51 µg/kg would be required to produce an urine excretion of 2 µg cadmium /24 hour by age 53. Thus, using child-specific absorption results in a difference of about 2-fold in the daily dose to produce the LOAEL effect. To be public health protective, OEHHA proposes to apply a child-protective factor of 3 to account for childhood absorption differences.

Calculation of the non-cancer chRD for cadmium is based on the following equation:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF} \times \text{CP}} = \frac{1 \mu\text{g/kg-day}}{30 \times 3} = 0.01 \mu\text{g/kg-day}$$

Where,

LOAEL = Lowest-observed-adverse-effect-level from Buchet et al., 1990.

UF = Uncertainty factor of 30 (10 for intra-human variability, 3 for LOAEL to NOAEL extrapolation because the LOAEL is based on the minimal effect observed and this is consistent with that applied to calculate the PHG).

CP = Child protective factor of 3 to account for the GI absorption difference between children and adults.

Accordingly, OEHHA is proposing a chRD of 0.01 µg/kg-day for cadmium's non-cancer effect to be used in school-site risk assessment instead of the U.S. EPA's RfD that did not account for a greater GI absorption of cadmium by children.

2.2 Chlordane

Chlordane is a cyclodiene pesticide, one of many organochlorine insecticides. Chlordane was used in large quantities until the U.S. EPA issued a notice of suspension except for use on subterranean structural termite control in 1976 (McConnachie and Zahalsky, 1992). It was banned for all uses in the United States in 1988, but it is still manufactured for export. Like DDT, it persists in the environment, and it is considered a priority persistent, bioaccumulative toxic (PBT) chemical by U.S. EPA (U.S. EPA, 2002).

Chlordane is not a pure chemical pesticide, and all studies investigating its toxicity or mechanism of action have used technical grade chlordane, which is a mixture. Infante et al. (1978) analyzed technical chlordane and reported that it contained 38-48 percent cis- and trans-chlordane, 3-13 percent heptachlor, 5-11 percent nonachlor, 17-25 percent other chlordane isomers, and a small amount of other compounds. Dearth and Hites (1991) identified 147 different compounds in a preparation of technical chlordane that included cis-chlordane (15 percent), trans-chlordane (15 percent), trans-nonachlor (15 percent), and heptachlor (3.8 percent).

OEHHA included chlordane in the "Compilation of Chemicals Potentially Found at School Sites" because it has been targeted by federal and state agencies as a chemical that may present environmental health risks. Chlordane appears on all but one of the chemical compilations that OEHHA has selected to identify chemicals that may be found at school sites. These compilations include:

- Soil contaminants identified at potential school sites in environmental investigations reviewed by the Department of Toxic Substances Control
- Toxic Air Contaminants (TACs) in California identified by OEHHA
- Analytes in the Department of Health Services/Air Resources Board (DHS/ARB) Portable Classroom monitoring study
- Analytes in the U.S. EPA National Health Exposure Assessment Study (NHEXAS)

Chlordane was placed by OEHHA in the compilation of "Candidate Chemicals Based on Critical Health Effects" because 1) it is on the Proposition 65 Developmental and Reproductive Toxin List and 2) a survey of recent scientific literature indicated that it possesses toxicity to organ systems that are developing in children, including the immune system, neuroendocrine and female reproductive systems (Ahmed, 2000; Barone et al., 2000; Barnett et al., 1990; Blyler et al., 1994; Brucker-Davis, 1998; DeRosa et al., 1998; Holladay et al., 2000; Holladay, 1999; Luster et al., 1990; Olea et al., 1998; Reigart, 1995; Spyker-Cranmer et al., 1982; Theus et al., 1992a and 1992b; Voccia et al., 1999). Chlordane exposure has also been associated with childhood cancer (Zahm et al., 1998.)

OEHHA staff prepared a PHG for chlordane in 1997 (OEHHA, 1997). The study on which the PHG is based showed that chlordane acted as an endocrine disruptor and

altered sex steroid-mediated behaviors when exposure occurred during gestation and lactation (Cassidy et al., 1994).

Endocrine disruptors, such as chlordane, are the subject of recent scientific and regulatory concern (U.S. EPA, 1998). They mimic or antagonize estrogens, androgens, and thyroid hormones, as well as their antagonistic analogs, and consequently disrupt the processes or tissues these hormones affect. Organ systems responsive to the sex steroids include the male and female reproductive organs, the central nervous system, and the immune system. The thyroid hormones affect most tissues (Bigsby, 1999). They are of particular concern in regard to children's health because they may disrupt the action of estrogen, androgen and thyroid hormones during critical periods of development and lead to permanent alterations in the reproductive, nervous, and immune systems that are developing during prenatal growth and childhood (Bigsby, 1999).

Existing Health Guidance Values

U.S. EPA Carcinogen Slope Factor: 3.5×10^{-1} per mg/kg-day

Chlordane is classified as B2; probable human carcinogen, using the 1986 Guidelines for Carcinogen Risk Assessment (Integrated Risk Information System (IRIS), 2003, <http://www.epa.gov/iris/subst/0142.htm#carc>). IRIS also reports that "under the 1996 Proposed Guidelines, it would be characterized as a likely carcinogen by all routes of exposure. These characterizations are based on the following summaries of the evidence available: (1) human epidemiology studies showing non-Hodgkin's lymphoma in farmers exposed to chlordane and case reports of aplastic anemia; chlordane associated with home use are inadequate to demonstrate carcinogenicity; (2) animal studies in which benign and malignant liver tumors were induced in both sexes of four strains of mice and occurred with an elevated, but not statistically significant, incidence in a fifth strain, as well as liver toxicity but no tumors in rats of two strains; and (3) structural similarity to other rodent liver carcinogens." The U.S. EPA oral slope factor is 3.5×10^{-1} per mg/kg-day. This value represents the geometric mean for five data sets with a range from individual data sets of 1.1×10^{-1} to 8.6×10^{-1} using the linearized multistage model (<http://toxnet.nlm.nih.gov/>). The EPA IRIS data base reported that the studies are of good quality and "the confidence is high that chlordane is a mouse liver carcinogen at dietary concentrations above 10 ppm. Although there is indication that the dose-response curve is sublinear in the dose region between 5 and 60 ppm, linearity at low doses cannot be ruled out on theoretical grounds. The tentative evidence is that the hematopoietic system, rather than the liver, is the target organ in humans."

U.S. EPA RfD: 5×10^{-4} mg/kg-day

The oral RfD established by U.S. EPA is 5×10^{-4} mg/kg-day based on a NOAEL of 0.15 mg/kg-day and LOAEL of 0.75 mg/kg-day in a mouse study (Khasawinah and Grutsch, 1989). The critical effect for the LOAEL was liver necrosis, with an uncertainty factor of 300 (10 for interspecies extrapolation, 10 for human variability, and 3 for deficiencies in

the database). The overall confidence given this RfD assessment is medium, both for the quality of the principal study and the sufficiency of the database. The principal study, assigned a confidence of medium, is a rat chronic oral study performed with relatively large group sizes, in which histopathological analyses on the known animal target tissue, the liver, were thoroughly performed. However, the discussion in IRIS stated that "available occupational studies, although limited, give no indication that the liver is a target organ in humans as a consequence of chronic exposure to low levels of chlordane" (<http://www.epa.gov/iris/subst/0142.htm#umfinhal>).

IRIS also reports that "recent evidence indicates that neurotoxicity, a known human endpoint in acute exposures, may be a relevant endpoint in chronic human exposures, and no chronic animals studies have examined neurotoxicity. Studies on pre-and postnatal animals indicating chlordane mimicry of sex-steroids raise reproductive concerns and no multigenerational reproductive studies, by any route, exist. Thus, there is some concern that the appropriate endpoints have not been examined adequately in the existing database." IRIS further states that "an area of scientific uncertainty in this assessment concerns the role of neurotoxicity, and possibly hematotoxicity, in chronic chlordane toxicity in humans." IRIS also notes that "another area of scientific uncertainty in this assessment concerns the toxicological significance of endocrine mimicry effects of chlordane. Toxicity data for this chemical include a study demonstrating biochemical and behavioral alterations consistent with technical chlordane (or its metabolites) mimicking male sex-steroids (Cassidy et al., 1994). That these effects could include reproductive behaviors is suggested in this study" (<http://www.epa.gov/iris/subst/0142.htm#quaoral>).

Studies on these endpoints would be of concern for children's health because accidental poisoning studies by chlordane in children have reported neuropsychiatric symptoms, which included learning disabilities, at an incidence four times that found in the general population according to the National Center for Health Statistics (Sherman, 1999). In 20 poisoned children, 20 percent had hematological problems and an additional 15 percent had hematological dyscrasias which may be early indicators of leukemia and aplastic anemia (Sherman, 1999).

OEHHA PHG: 0.02 ppb (a safe dose of 1×10^{-5} mg/kg-day)

The PHG developed by OEHHA is 1×10^{-5} mg/kg-day, or 0.02 ppb in drinking water, based on a LOAEL of 0.1 mg/kg-day because of disruption of sex steroid-mediated behaviors in rat identified by Cassidy et al., 1994. The health-protective drinking water concentration for carcinogenic endpoints is calculated to be 0.03 ppb. The U.S. EPA drinking water unit risk is 1×10^{-5} per ($\mu\text{g/L}$) which translates into risk levels of 10^{-4} to 10^{-6} at concentrations of 3 ppb and 0.03 ppb, respectively (U.S. EPA, 1996).

Current Evaluation Results

Chlordane has been shown to have critical effects on two developing systems due to endocrine disruption. It adversely affects the developing immune system of mice (Spyker-Cranmer et al., 1982; Barnett et al, 1985a; Barnett et al., 1985b; Barnett et al.,

1990; Theus et al., 1992a; Theus et al., 1992b; Blyler et al., 1994), and it alters sex-mediated neurobehavioral endpoints (Cassidy et al., 1994). These effects on the developing endocrine and immune systems show an age-related susceptibility to chlordane. Adult animals exposed to similar or higher doses of chlordane did not show similar effects (Johnson et al., 1986; Barnett et al., 1990; Barnett, 1997).

An endocrine disruptor such as chlordane can act at the level of the hypothalamic-pituitary-adrenal (HPA) axis, disrupting the negative feedback loop between the brain and the immune system. Under normal physiological conditions, activation of the immune system stimulates the release of cytokines, which can then act on the HPA axis to trigger the release of corticosterone. However, if increased levels of corticosterone are released, due to the presence of endocrine disruptors, these high corticosterone levels produce immuno-suppression on virtually all levels of the immune system (Gaillard and Spinedi, 1998; Morale et al., 1995), including depression of the delayed-type hypersensitivity response (Okimura et al., 1986), suppression of granulocyte and macrophage migration (Mizobe et al., 1997), and inhibition of hematopoietic cytokines such as IL-3 and CFU-GM (Gaspar Elsas et al., 2000 and Mucha et al., 2000).

In addition, high levels of glucocorticoids can disrupt all aspects of the hypothalamic-pituitary-gonadal (HPG) axis, including reproductive behavior and the synthesis and release of sex steroids (Viau, 2002) and can interfere with the functioning of the hippocampus, the part of the brain responsible for learning and memory (Kim and Diamond, 2002). It has been shown that the release of adrenocorticotrophic hormone (a hormone that stimulates the release of corticosterone) is associated with increased sexual excitation in male rats (Szechtman et al., 1974), and Bowman and colleagues (2001) demonstrated that female rats exposed to stress-induced increases in corticosterone levels showed altered spatial memory performance.

A key finding, suggesting that chlordane disrupts the HPA and HPG axis, was the observation that exposure of the dihybrid mice dams to 0.16 mg/kg-day of analytical reference standard chlordane (which has the same products as technical grade chlordane) from 0-18 days of gestation (Table 2.2.1) produced significantly elevated corticosterone in male and female offspring when they were assayed as adults at 100 and 400 days of age (Cranmer et al., 1984). This indicated a permanent (or long-lasting) effect on the offspring. This dose of technical grade chlordane also reduced metabolism of corticosterone in female BALBc mice and elevated resting plasma corticosterone in male mice at 100 days of age (Spyker-Cranmer et al., 1982). Corticosterone, like cortisol, is synthesized from progesterone by a series of hydroxylations. Testosterone is also synthesized from progesterone, and estradiol is synthesized from testosterone (Stryer, 1981). Chlordane can alter corticosterone levels, and corticosterone is an intermediate in the synthesis of steroids. By this mechanism, chlordane can affect the developing immune system, and it could permanently alter characteristic differences between males and females in non-reproductive and reproductive measures (such as body weight, development of sexual organs, circulating steroid levels, mating behavior, spatial abilities, activity level, or mixed function oxidase levels (Weiss, 2002). The endocrine

disruptive effect of chlordane appears to be corroborated by the study of Cassidy and colleagues (Cassidy et al., 1994) in which a dose of 0.1 mg/kg-day chlordane to the dam and then to the pups until postnatal day 80 caused sex steroid-mediated changes in gender-specific behaviors and functions (Cassidy et al., 1994). There was a dose-responsive decrease in plasma testosterone, which was significant at 5 and 0.5 mg/kg-day, but not significant at 0.1 mg/kg-day.

Table 2.2.1 Summary of Significant Studies on Chlordane

Reference	Protocol	Doses	Critical Effects
Spyker-Cranmer et al., 1982	Pregnant BALB/C mice were dosed until day 18 of gestation and pups nursed on their natural mothers until 21 days of age	0.16 and 8 mg/kg maternal body weight	Delayed Type Hypersensitivity (DTH) was significantly depressed at 8 mg/kg; and depressed but not significantly at 0.16 mg/kg
Cranmer et al., 1984	Pregnant F2 Dihybrid mice were dosed until day 18 of gestation and pups nursed on their natural mothers until 21 days of age.	0.16 and 8 mg/kg maternal body weight	Plasma corticosterone was significantly elevated at 101 days and 400 days in male mice whose mothers were dosed with 0.16 mg/kg-day. It was elevated in female mice at 400 days of age
Barnett et al., 1990	Pregnant BALB/C mice were dosed until day 18 of gestation and pups nursed on their natural mothers until 21 days of age	4 and 8 mg/kg maternal body weight	Hematopoietic stem cells (CFU-GM and CFU-S) in offspring were significantly decreased at 100 and 200 days of age. Adult animals treated with 8 mg/kg chlordane did not have any decrease or differ from controls.
Cassidy et al., 1994	Sprague-Dawley CD rats were dosed from Day 4 of gestation until Day 21 of lactation. Pups were dosed individually from post natal day (PND) 22 until PND 80.	0.1, 0.5, and 5 mg/kg maternal body weight	Females had significant improvements in spatial abilities in the Cincinnati Water Maze test at all doses, males exhibited dose-dependent increases in male-typical mating behavior, and both exhibited maximum response to auditory startle at 0.1 mg/kg when tested at 80 days.

The effects of chlordane on the developing immune system, and their persistence into adulthood, were demonstrated in a series of related studies using prenatal and postnatal exposure to chlordane (Spyker-Cranmer et al., 1982; Barnett et al, 1985a; Barnett et al., 1985b; Barnett et al., 1990; Blyler et al., 1994; Theus et al., 1992a; Theus et al., 1992b). The experimental protocol common to all the studies was to feed pregnant mice 0.3 mg of peanut butter which was spiked with technical chlordane to provide a maternal dose of 0.16 mg/kg, 4 mg/kg, 8 mg/kg or 16 mg/kg maternal body weight, although not all doses were used in the assay of each immune system parameter. The pups were allowed to

nurse through day 21. Assays of immune system parameters were performed at various postnatal days, ranging from day 42 to day 200, although not each immune system parameter was assayed at each postnatal time point. Chlordane is fat-soluble, having a log K_{ow} (octanol-water coefficient) of 5.16, so it should be readily transferred from plasma to milk. The total amount of chlordane reaching the pups was determined to be 3.5 mg/kg by analyzing chlordane and its metabolites in the conceptus and in pups at intervals during gestation and through the end of lactation (Theus et al., 1992)

Immune responses, such as delayed type hypersensitivity (DTH), were significantly depressed in offspring at 100 days of age after exposure in utero to a maternal dose of 8 mg/kg-day body weight. A maternal dose of 0.16 mg/kg-day also depressed DTH, although not significantly (Spyker-Cranmer et al., 1982). Pups received chlordane from 0-18 days of gestation, when the mother was dosed, and through 21 days of nursing, when dosing of the mother had ceased. Thus, the pup's exposure dose was actually lower than either 8 mg/kg-day or 0.16 mg/kg-day for its exposure duration.

A decreased DTH response occurs due to functional abnormalities in T lymphocytes, specifically the CD4 T_H1 helper cells. There are three kinds of effector T cells: cytotoxic CD8 T cells, which kill infected cells, and two kinds of CD4 T cells (T_H1 , or T helper 1, and T_H2) with different functions (Parham, 2000). It is noteworthy that a decrease in the number of helper/inducer T cells is found in acquired immune deficiency (AIDS) disease, and this decrease is thought to allow infections such as Kaposi's sarcoma, *Pneumocystis carinii* pneumonia, and cytomegalovirus (CMV) retinitis (Lane and Fauci, 1985).

A critical effect on the developing immune system was a significant reduction in the number of granulocyte-monocyte committed stem cells (CFU-GM) and multipotential stem cells (CFU-S) in adult offspring (100 and 200 days of age) of pregnant mice exposed to 4 mg/kg and 8 mg/kg chlordane (Barnett et al., 1990). The bone marrow of offspring exposed to 4 or 8 mg/kg-day chlordane had 63 percent and 75 percent of control CFU-GM at 100 days of age, and at 50 percent and 77 percent at 200 days of age in offspring exposed to 4 mg/kg-day. The multipotential stem cells (CFU-S) were similarly depressed. Female and male offspring exposed prenatally to 8 mg/kg chlordane had 67 percent and 64 percent respectively of control CFU-S, while those exposed to 4 mg/kg-day chlordane had 78 percent and 87 percent of control CFU-S. At 200 days of age the bone marrow CFU-S in female offspring was almost unchanged, and that in males was still significantly reduced. This significant reduction in stem cells which could divide and differentiate into mature functional blood cells could produce life-threatening consequences. This decrease, as well a decrease in Interleukin-3 (IL-3) stem cells, was confirmed to be present at 42-49 postnatal days when specific recombinant growth factors were utilized (Blyler et al., 1994). IL-3 is a cytokine produced by T helper (T_H1 and T_H2) cells and it is a growth factor for multipotential progenitor hematopoietic cells (Parham, 2000). This toxicity endpoint is significant for humans because blood dyscrasias and bone marrow failures have been reported in people following accidental dermal or inhalation exposure to chlordane at unspecified dose levels (Infante et al., 1978; Klemmer et al., 1977; Furie and Trubowitz, 1976).

Clonogenic assays for hematopoietic progenitors have been used in clinical hematology for 30 years (Parent-Massin, 2001) and in research to predict adverse effects of drugs or toxicants, as the rapid rate of cell renewal and differentiation makes the hematopoietic system a susceptible target for xenobiotic toxicity. Xenobiotics that interfere with cell proliferation and differentiation can lead to "bone marrow failure." The two major groups of bone marrow failure are aplastic anemia, where the failure lies in the pluripotent stem cell (colony forming unit – stem cell or CFU-S), and single cytopenia, where the failure lies in the stem cell for one of the committed cell lines, such as the granulocyte/monocyte cell line, the CFU-GM (Parent-Massin, 2001). Most bone marrow failures are characterized by inadequate production of blood cells and, if severe, death of the organism results because existing numbers of stem cells have an inadequate ability to produce mature cells to provide oxygen (anemia), clot blood (thrombocytopenia), or to protect the organism from infection.

Endocrine disruptors such as chlordane can affect neuroendocrine/neurobehavioral endpoints, as well as immune endpoints. The studies of Cassidy and colleagues (Cassidy et al., 1994) confirmed that perinatal chlordane could mimic sex steroids and /or change their levels to masculinize sexually dimorphic functions and behaviors. They dosed pregnant rats with technical chlordane at 0.1 mg/kg, 0.5 mg/kg, and 5 mg/kg during gestation, and they dosed the offspring during 21 days of lactation and from postnatal day 22 to postnatal day 80. Female offspring committed fewer errors than controls in three assays of cognitive and spatial ability in the Cincinnati Water Maze test, appearing to behave more like males, and male offspring exhibited dose-dependent increases in male-typical mating behaviors. The differences in behavior compared to unexposed animals demonstrate that sexual differentiation of the neuroendocrine system has been altered by early life exposure to chlordane. The neuroendocrine-gonadal axis regulates the developmental organization and adult expression of behaviors critical for mammalian survival and reproduction (competitive aggression, exploration, and sexual and parental behaviors), so neurobehavioral alterations induced by endocrine disruptors may impact the survival and fitness of an individual in its environment (Palanza et al., 2002)

Recommendation

Based on studies that describe endocrine disruption and effects on the developing hematopoietic, immune and neuroendocrine systems in young animals, OEHHA recommends that a chRD be developed. The critical effects are alterations in characteristic behavior differences between males and female at doses of 0.1 mg/kg-day maternal body weight and 0.1 mg/kg-day pup weight (Cassidy et al., 1994), and disruption of the hematopoietic and immune systems at a maternal dose as low as 0.16 mg/kg-day maternal body weight (Cranmer et al., 1984).

OEHHA recommends that a non-cancer child-specific RD be calculated on the study by Cassidy and colleagues (Cassidy et al., 1994) that showed that a chlordane dosage of 0.1 mg/kg-day (to the pups, as well as the mother) disrupted sex hormone mediated

behaviors. Differences from control were significant at the lowest dose, indicating that 0.1 mg/kg dose is a LOAEL. Because these effects are indicative of endocrine disruption, it is possible that the hematopoietic/immune effects described in the other studies may also occur at this low dose.

Calculation of the non-cancer child-specific RD for chlordane is based on the following equation:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF}} = \frac{0.1 \text{ mg/kg-day}}{3000} = 3.33 \times 10^{-5} \text{ mg/kg-day}$$

Where,

LOAEL = Lowest Observed Adverse Effect Level (Cassidy et al, 1994)

UF = Uncertainty factors of 3000 (10 for LOAEL to NOAEL, 10 for interspecies extrapolation, 10 for human variability, and 3 for inadequate database for hematotoxicity, immunotoxicity, neurotoxicity, and the lack of a valid developmental study).

Accordingly, OEHHA is proposing a non-cancer chRD of 3.3×10^{-5} mg/kg-day for chlordane.

Uncertainty and Modifying Factors

OEHHA has applied the additional uncertainty factor 3 for inadequacies in the database for each of three endpoints, hematotoxicity, neurotoxicity, and reproductive toxicity that data suggest may be of concern to human children. This uncertainty factor has been applied in accordance with U.S. EPA (1994) and Renwick et al., (2000), that it is appropriate "if a valid developmental toxicity study was not performed", or "if the study did not examine all developmental endpoints". In the discussion of chlordane on the IRIS database, U.S. EPA noted that "studies on pre-and postnatal animals indicating chlordane mimicry of sex steroids raise reproductive concerns and no multigenerational reproductive studies, by any route, exist. Thus, there is some concern that the appropriate endpoints have not been examined adequately in the existing database" (<http://www.epa.gov/iris/subst/0142.htm#umfinhal>).

The U.S. EPA RfD was based on hepatic necrosis in mice, even though the discussion on the IRIS database noted that "occupational studies, although limited, give no indication that the liver is a target organ in humans as a consequence of chronic exposure to low levels of chlordane." U.S. EPA reduced confidence in their RfD noting that "an area of scientific uncertainty concerns the role of neurotoxicity and possibly hematotoxicity in chronic chlordane toxicity in humans" (<http://www.epa.gov/iris/subst/0142.htm#umfinhal>). Neurotoxicity and hematotoxicity

have been reported as principal endpoints of acute chlordane toxicity in both experimentally poisoned animals and accidentally poisoned humans (Grutsch and Khasawinah, 1991; Fleming and Timmeny, 1993). The uncertainty increases when considering exposure of children, rather than adults, because these organ systems are undergoing critical development during childhood.

The reduced numbers of hematopoietic stem cells in offspring, after they had reached maturity, from exposure to a 4 mg/kg-day maternal dose (Barnett et al., 1990a), provides low confidence that a LOAEL which produced minimally significant adverse hematological effects was identified. Immune system toxicity from chlordane is a concern because a report of outcomes from exposure of 20 children to chlordane from pesticide applications noted that 20 percent had hematological problems and an additional 15 percent had hematological dyscrasias (Sherman, 1999). Blood cell dyscrasias are a concern to clinicians because they may later manifest themselves as leukemias and aplastic anemias. The outcome of reduced numbers of stem cells can be bone marrow failure.

The database on chlordane toxicity to children is also considered inadequate because no animal studies have adequately assayed neurotoxicity due to low chlordane exposure concentrations, and there are case reports of human neurotoxicity (Kilburn and Thornton, 1995; Kilburn, 1997). Al-Hachim and Al-Baker (1973) reported that when pregnant mice were exposed to 1 mg/kg-day technical chlordane for only seven consecutive days the pups had poor learning ability or altered motivation in the assay for conditioned avoidance response, raised seizure threshold, and increased exploratory activity. Reports of accidental human exposure to termiticides have resulted in neurobehavioral impairments in adults (Kilburn and Thornton, 1995; Kilburn, 1997) and 70 percent of 20 child patients exposed to chlordane had neuropsychiatric symptoms, which included learning disabilities at an incidence four times that found in the general population, according to the National Center for Health Statistics (Sherman, 1999). School-age children were reported to develop new problems: headaches, visual difficulties, hyperactivity, learning disabilities, frequent ear-nose-throat and chest problems, and gastrointestinal disturbances (Sherman, 1999).

The Food Quality Protection Act required a 10 fold safety factor be applied "for infants and children" for pesticide risk assessments "to take into account...completeness of the data with respect to ... toxicity" and OEHHA utilized the 10 fold factor in creating a public health goal (PHG) for chlordane. However, U.S. EPA has been limiting the composite factor to 3,000 when human-equivalent doses are used (U.S. EPA, 1994). As the low dose in the Cassidy et al. (1994) study, which forms the basis for the child-specific RfD, was based on serum levels found in the United States at the 99th percentile (i.e. 1% of the U.S. values are higher), OEHHA decided to utilize only a 3-fold modifying factor to account for the inadequacies in the database.

Additional Comments/Studies:

The experiments from Barnett and colleagues (Spyker-Cranmer et al., 1982; Barnett et al., 1985a; Barnett et al., 1985b; Barnett et al., 1990; Theus et al., 1992a; Theus et al., 1992b; Blyler et al., 1994) support an equivalent or lower dose than the one derived from the Cassidy et al., 1994 study. The experimental protocol of Barnett and colleagues differed from that of Cassidy et al., 1994, in that the pup was not individually dosed. A maternal dose of 8 mg/kg-day was reported to produce a *total* dose of 3.5 mg/kg of chlordane in the pup (Theus et al., 1992). If an equal fraction of 3.5 mg/kg dose were delivered each day of the 18 days of gestation, when the mother was dosed, and the 21 days of lactation, when the mother was not dosed, the pup would receive 0.09 mg/kg-day over the 39 day period. This estimated pup dose is very close to the 0.1 mg/kg-day dose that Cassidy et al. (1994) gave to dams, *and* to pups following weaning and until sacrifice on day 80.

The experiment of Cranmer et al. (1984) suggests that the LOAEL could be lower than 0.1 mg/kg-day. In this study, the dams were dosed with either 0.16 mg/kg-day or 8 mg/kg-day chlordane during gestation. As noted above, the maternal dose of 8/mg/kg-day was shown to produce a total dose of 3.5 mg/kg in the pups when the concentration of chlordane metabolites analyzed on successive days during the 39 days of gestation and lactation were totaled. The average daily dose to the pup was 0.09 mg/kg-day. If the toxicokinetics from the 0.16 mg/kg-day maternal dose is proportional to that from the 8 mg/kg-day maternal dose, then the pups of a dam dosed with 0.16 mg/kg-day (Cranmer et al., 1984) would receive 0.0018 mg/kg-day. Emerging understanding of the hypothalamic-pituitary-adrenal (HPA) axis substantiates the possibility that a low dose may impair the developing immune system.

2.3 Heptachlor/Heptachlor Epoxide

Heptachlor (heptachlorodicyclopentadiene) was used primarily as an agricultural insecticide from 1952 to 1976, as a narcissus bulb and seed treatment and insecticide for fire ant control on pineapple crops until 1976, and as a treatment for subterranean termites until 1987 (Fendick et al., 1990). In 1985, heptachlor alone or in combination with chlordane, accounted for 60-65 percent of the termiticides used in the U.S. (EPA 1987 – see Fendick et al.). In 1987, the EPA and the Agency for Toxic Substances and Disease Registry (ATSDR) classified heptachlor as a priority Group 1 Hazardous Substance, making Superfund money available for cleanup of heptachlor-contaminated sites.

Technical heptachlor contains heptachlor plus related reaction products in approximately a 5:2 ratio (Fendick et al., 1990). Heptachlor is a moderately persistent compound (Ware et al., 1990). In the soil it undergoes multiple transformation and degradation reactions by at least three pathways: epoxidation, hydrolysis, and dechlorination. Epoxidation generates the more persistent and bioaccumulative metabolite, heptachlor epoxide, while hydrolysis is a detoxification reaction (Fendick et al., 1990). U.S. EPA has considered heptachlor and heptachlor epoxide two separate chemicals, and it has established separate RfDs, probably because heptachlor epoxide absorbs strongly to soil and is extremely resistant to biodegradation (Hazardous Substances Databank, <http://toxnet.nlm.gov>), persisting in soils for a long time (Ware, 1988).

OEHHA included heptachlor/heptachlor epoxide in the “Compilation of Chemicals Potentially Found at School Sites” because it has been targeted by federal and state agencies as a chemical that may present environmental health risks. Heptachlor appears on all but two of the chemical compilations that OEHHA has selected to identify chemicals that may be found at school sites. These compilations include:

- Soil contaminants identified at potential school sites in environmental investigations reviewed by the Department of Toxic Substances Control
- Toxic Air Contaminants (TACs) in California identified by OEHHA
- Analytes in the U.S. EPA National Health Exposure Assessment Study (NHEXAS)

OEHHA also included heptachlor/heptachlor epoxide in the compilation of “Candidate Chemicals Based on Critical Health Effects” because heptachlor epoxide is on the Proposition 65 Developmental and Reproductive Toxicant List, and a survey of recent scientific literature indicated that heptachlor and heptachlor epoxide are toxic to organ systems that are developing in children. These organ systems are the immune, nervous, endocrine, and male and female reproductive systems (Brucker-Davis, 1998; DeRosa et al., 1998; Moser et al., 2001; Nicolopoulou-Stamati et al., 2001; Rani et al., 1995; Smialowicz et al., 2001; Voccia et al., 1999). Heptachlor and heptachlor epoxide were also reported to produce cancer (Zahm et al., 1998 and <http://toxnet.nlm.nih.gov>).

Existing Health Guidance Values

U.S. EPA Carcinogen Slope Factor: 4.5 per mg/kg-day

Heptachlor is classified by EPA as a B2, probable human carcinogen, based on several studies. Davis (1965) fed groups of 100 male and 100 female C3H mice diets with 0 or 10 ppm heptachlor (purity not specified) for 2 years. Survival was low, with 50 percent of the controls and 30 percent of the treated mice surviving until the end of the experiment. A two-fold increase in benign liver lesions over the controls was reported. After a histologic reevaluation, Reuber (as cited in Epstein, 1976), as well as four other pathologists, remarked a statistically significant increase in liver carcinomas in the treated male (64/87) and female (57/78) groups by comparison to controls (22/73 and 2/53 for males and females, respectively). The NCI (1977) reported a significant dose-related increase of hepatocellular carcinomas in male and female B6C3F1 mice.

U.S. EPA RfD: 5×10^{-4} mg/kg-day

The current oral RfD for heptachlor given by U.S. EPA in 1991 is 5×10^{-4} mg/kg-day (<http://toxnet.nlm.nih.gov>). This value was derived from a three ppm dietary NOAEL in a two-year rat feeding study where the critical effect was liver weight increase (Velsicol Chemical, 1955, cited by U.S. EPA <http://toxnet.nlm.nih.gov/>). The LOAEL in this study was 5 ppm or 0.25 mg/kg-day and an uncertainty factor of 300 was employed. EPA reports that there is low confidence that this RfD is accurate because the principal study is of low quality; the database on chronic toxicity is incomplete. There are no teratology, reproductive, or studies in young animals.

An RfD for heptachlor epoxide was based on a study in which adolescent dogs were fed heptachlor epoxide for 60 weeks (Dow Chemical Company, 1954). The LOAEL of 0.5 ppm (0.0125 mg/kg-day) was based on an increased liver-to-body weight ratio in both males and females as a critical effect (Dow Chemical Co., 1958, cited in U.S. EPA IRIS online file, <http://toxnet.nlm.nih.gov/>). An uncertainty factor of 1000 was employed. EPA indicates there is low confidence that the RfD is accurate because the principal study is of low quality, and the chronic toxicity studies are of low quality. There were no rat or rabbit teratology studies.

OEHHA PHG: 8 ppt (a safe dose of 1×10^{-4} mg/kg-day)

OEHHA staff prepared a Public Health Goal (PHG) for heptachlor of 8×10^{-6} mg/L drinking water, based on a cancer slope factor of $4.1 \text{ mg/kg-day}^{-1}$ and a 1×10^{-6} cancer risk (OEHHA, 1999b). Heptachlor exposure produced a dose-related increase in the incidence of hepatocellular carcinoma in male and female B6C3F1 mice (NCI, 1977) and hepatocellular carcinoma in male and female C3H mice (Davis, 1965).

OEHHA (1999) considered two studies when non-cancer effects were reviewed. The first was the two-year rat feeding study where the critical effect was liver weight increase that was used by EPA when it last revised the heptachlor RfD (Velsicol Chemical, 1955, cited by U.S. EPA, <http://toxnet.nlm.nih.gov>). Uncertainty factors of 10 for interspecies variability and 10 for interindividual variability were used. The second study (Cassidy et al., 1994) reflected the recent concern about the endocrine disruption effects of chlorinated cyclodiene and other chlorinated pesticides. The critical effect in this study was the alteration of sex steroid-mediated behaviors by prenatal and early-in-life exposure to 0.1mg/kg/day technical chlordane which contains 10percent heptachlor. In this calculation, the uncertainty factors are: LOAEL to NOAEL extrapolation (10), interspecies variability (10), and interindividual variability (10), resulting in a "safe" non-cancer human dose of 1×10^{-4} mg/kg/day

Current Evaluation Results

The effects of heptachlor that are specific for children are its disturbance of the development of the endocrine system and of the organs that respond to endocrine signals when exposure occurs during prenatal and/or early postnatal life (Colborn, 1993). These effects are permanent.

Contamination of the commercial milk supply of Oahu, Hawaii, with heptachlor for 15 months, from 1981 to 1982, and the subsequent finding of heptachlor epoxide in human milk, prompted new studies on rats to look for possible effects of heptachlor and its persistent primary metabolite at the concentrations to which children were exposed. The Hawaii Heptachlor Research and Education Foundation (HHREF) cosponsored these studies with the U.S. EPA and NIEHS in order to evaluate many aspects of the impact of heptachlor exposure during the perinatal/juvenile period of development, using a broad battery of tests of immune and reproductive system function.

The doses (0, 0.3, 3, or 30 mg/kg-day of 99% pure heptachlor) employed were adjusted so that the low dose gave milk values of heptachlor epoxide that approximated the 95th percentile of human milk heptachlor and heptachlor epoxide values in Oahu, Hawaii in 1981 (Baker et al., 1991; Siegel, 1988 in Smialowicz et al., 2001). The period of exposure was designed to approximate the last trimester of pregnancy through 18 years of age in humans. The experimental design for the studies of endocrine disrupting effects on immune, neurobehavioral, and reproductive is given in Figure 2.3.1.

Figure 2.3.1 Experimental Design

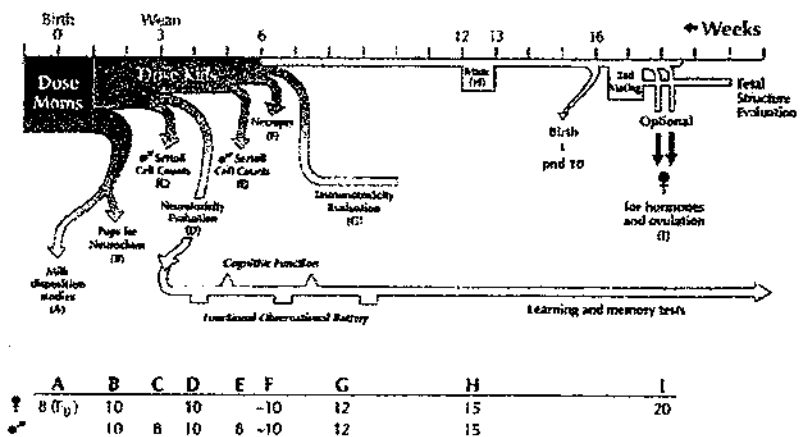

Figure taken from Moser et al., 2001 and Smialowicz et al., 2001)

The results of one subset of this study (Smialowicz et al., 2001) indicated that exposure of rats to heptachlor during the last trimester of gestation through puberty adversely affects adult functioning of the immune system by suppressing the primary IgM and secondary IgG antibody response in male offspring. Rats were exposed to 0, 0.3, 3, or 30 mg/kg-day from gestation day 12 to postnatal day 7, followed by direct dosing through postnatal day 42. The LOAEL was identified as 0.3 mg/kg-day because the primary IgM antibody response to Sheep Red Blood Cells (SRBCs), as measured by enzyme linked immunosorbent assay (ELISA) was suppressed at 8 weeks of age and at 21 weeks of age. At the same dose, the secondary IgG response was also suppressed at 25 weeks of age. These responses require three major immune cell types: macrophages, the CD4+ T-helper cells, and B cells. Alterations in or dysfunction of any of these cells and cell interactions can result in aberrant antibody production (Luster et al., 1988 in Smialowicz, 2001). The suppression of these T cell-dependent antibody responses persisted through the first six months of life at all doses employed, including the lowest dose, 0.3 mg/kg-day, which was administered through 6 weeks of age.

The response to SRBC is one of the most sensitive functional parameters in animals exposed to immunosuppressants (Luster et al., 1992). Consequently, it is included in the battery of tests required by the Federal Insecticide, Fungicide, and Rodenticide (FIFRA) guidelines for detection of immunosuppressants (Smialowicz, 2001). In both animals and humans, T-cell dependent responses are involved in protection against viral, bacterial, and parasitic infections (Blanden, 1974 in Smialowicz, 2001). Consequently, the suppression of the primary IgM and secondary IgG antibody responses suggests potential increased susceptibility to infectious diseases.

In another subset of rats from the same large study, heptachlor produced significant differences in tests for cognitive abilities that are associated with the development of neuroendocrine pathways (Moser et al., 2001). Rats were evaluated for neurological and behavioral alterations using a functional observational battery (FOB), an automated measure of motor activity, passive avoidance, and a Morris water maze test (Moser et al., 2001). Rats dosed prenatally and postnatally until day 21 had changes in activity measures, but those in which dosing continued until day 42 had alterations in autonomic, neuromuscular, and excitability measures. The most pronounced effects of heptachlor occurred in rats treated until day 42 and tested with the Morris water maze test. The Morris water maze test (Morris, 1984) was devised to resolve theoretical controversies about the basis of spatial and working memory. Normal rats learn very quickly to swim directly towards a platform from any starting position at the circumference of a pool. The accurate directionality of their escape behavior provide evidence that the rats escape by learning the position of the platform relative to distal cues. Thus, their performance can be compared to those of animals exposed to potential neurotoxins to assay spatial learning and memory (Morris, 1984).

Heptachlor exposure slowed acquisition of the spatial task and impaired recall during probe trials: the treated male rats at all dose levels did random searching for the platform, rather than developing an efficient search strategy. Working memory, which was assayed by requiring the rats to learn a new position for the platform each day, was significantly decreased in the low dose (0.03 mg/kg-day) male rats which had been dosed with heptachlor prenatally and postnatally until Day 21. The escape latency (mean time to find the new location) was 27.9 seconds compared to 20.5 seconds in control (Smialowicz, et al., 2001).

Cyclodiene pesticides bind to the chloride channel portion of the receptor for the neurotransmitter gamma aminobutyric acid (GABA)_A, block the inhibitory actions of and thus affect a variety of neurological functions in both adult and young animals (Abalis et al., 1986; Cole and Casida, 1986; Gant et al., 1987 in Moser, 2001). Acute actions of cyclodiene pesticides include excitation, hyperstimulation, and convulsions (Cole and Casida, 1986; Fendick et al., 1990). In young mammals, the development of the nervous system is quite protracted, and specific processes of migration, proliferation, and differentiation occur from gestation throughout childhood and into adolescence. These processes occur in sequence, so disturbance of earlier processes can disrupt later developmental events. Cyclodiene insecticides alter expression of the GABA_A receptor. Since the neurotransmitter, GABA, influences development of serotonergic, dopaminergic, and cholinergic neurotransmitter systems, cyclodiene pesticides may produce long-lasting alterations in brain function (Lauder et al., 1998 in Smialowicz et al., 2001).

Recommendation

Heptachlor:

The experiments of Smialowicz et al. (2001) and Moser et al. (2001) describe several critical effects in young male rats at a LOAEL of 0.03 mg/kg-day heptachlor during the last half of gestation and the first 21 or 42 postnatal days. The most significant effects include suppression of the primary IgM and secondary IgG antibody response (Smialowicz et al., 2001), and decreased performance on measures of cognitive function, such as impaired recall (Moser et al., 2001).

Technical grade heptachlor and chlordane are mixtures of pure compound plus related reaction products (Ware, 1990). The PHG developed by OEHHA in 1999 utilized a study (Cassidy et al., 1994) that described a disruption of sex-steroid mediated behaviors in female mice at a dose of 0.01 mg/kg-day of technical grade chlordane, which contains 10 percent heptachlor. More recent studies (Smialowicz et al., 2001, Moser et al., 2001), which used heptachlor of 99 percent purity, have allowed OEHHA staff to develop the chRD for heptachlor without the ambiguity associated with testing a mixture.

Calculation of the non-cancer chRD is based on the following equation:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF}} = \frac{0.03 \text{ mg/kg-day}}{1000} = 3.0 \times 10^{-5} \text{ mg/kg-day}$$

Where,

LOAEL = Lowest Observed Adverse Effect Level from Smialowicz et al., 2001 and Moser et al., 2001

UF = Uncertainty factor of 1000 (10 for LOAEL to NOAEL, 10 for inter-species extrapolation, 10 for human variability)

Accordingly, OEHHA is proposing a non-cancer chRD of 3.0×10^{-5} mg/kg-day for heptachlor.

Heptachlor Epoxide:

Heptachlor has not been used since 1987 when its use was restricted. Heptachlor in the soil undergoes multiple transformation and degradation reactions, and epoxidation generates the more persistent and bioaccumulative metabolite, heptachlor epoxide (Fendick et al., 1990), so children at school sites may be exposed to heptachlor epoxide.

The principal study used by U.S. EPA to calculate an RfD (<http://toxnet.nlm.nih.gov>) was a 60-week dog feeding study (Dow Chemical Co., 1958) in which the LOAEL was an increased liver-to-body weight ratio. Although liver-to-body weight ratio is not a child-

specific endpoint, the exposure period began in adolescence and continued into young adulthood.

Since adolescent animals were exposed, OEHHA has decided to utilize the same study and the same uncertainty factors to calculate a non-cancer child-specific RD as the U.S. EPA RfD:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF}} = \frac{0.0125 \text{ mg/kg-day}}{1000} = 1.3 \times 10^{-5} \text{ mg/kg-day}$$

Where,

LOAEL = Lowest Observed Adverse Effect Level from Dow Chemical Co, 1958

UF = Uncertainty factor of 1000 (10 for LOAEL to NOAEL, 10 for inter-species extrapolation, 10 for human variability)

Accordingly, OEHHA is proposing a non-cancer chRD of 1.3×10^{-5} mg/kg-day for heptachlor epoxide.

2.4 Methoxychlor

Methoxychlor, 2,2-bis(p-methoxyphenyl)-1,1,1-trichloroethane, is structurally related to DDT. Because of its lower toxicity and bioaccumulation potential, methoxychlor became an attractive replacement of DDT (ATSDR, 1994). It was registered as an insecticide against a wide range of pests, including houseflies, mosquitoes, cockroaches, and various arthropods commonly found on fields crops, vegetables, fruits, stored grain, livestock, and domestic pets.

While DTSC's school site review efforts continue, methoxychlor has already been detected at a school site. Recent studies show that demethylated metabolites of methoxychlor are an endocrine disruptor. Accordingly, OEHHA believes it is important to further review methoxychlor pursuant to Health and Safety Code Section 901(g). As endocrine disruptors, methoxychlor metabolites may have adverse effects on different developing organ systems. These chemicals may disrupt the development and functioning of the female reproductive system, and the brain, and the male reproductive system (vom Saal et al., 1983, 1997; Nonneman et al., 1992; Hess et al., 1997). As such, the effect of methoxychlor or its metabolites could affect the development of school children. Moreover, earlier studies may have inadequately characterized the dose-response relationship of methoxychlor (NTP, 2001). In reviewing environmental estrogens, the NTP Peer Review Subpanel found that overall the classic estrogenic activity of methoxychlor was limited to doses greater than 5 mg/kg-day because testing at lower doses had not been incorporated into the experimental design. An updated review of the pertinent literature is necessary to ensure that the appropriate LOAEL or NOAEL will be considered in setting a child-specific guidance value.

Pertinent Guidance Values

U.S. EPA RfD: 0.005 mg/kg-day

U.S. EPA used the 1986 Kincaid Enterprises, Inc. study to establish its RfD. Young adult female New Zealand White rabbits were assigned into 3 dose groups of 17 animals each, 5.01, 35.5, and 251.0 mg/kg-day, and a control group (a total of 68 animals). The females were artificially inseminated and the day of insemination considered as gestation day 0. All animals were dosed from days 7 through 19 of gestation. All surviving dams were sacrificed on gestation day 29.

Maternal toxicity was observed as excessive loss of litters (abortions) and statistically significant decreases in body weight in the mid- and high-dose groups, and the deaths in the high dose group. No specific toxicity was noted in the low dose (5.01 mg/kg-day), which was deemed to be the NOAEL.

An uncertainty factor of 1000 was applied to the NOAEL in developing the RfD; of which 100 was used to account for the inter- and intra-species differences and an

additional 10 was used to account for the poor quality of the critical study and for the incomplete database on chronic toxicity.

OEHHA PHG: 0.03 mg/L (a safe dose of 0.005 mg/kg-day)

In reviewing literature for the purpose of establishing a Public Health Goal (PHG) for methoxychlor in drinking water (OEHHA, 1999c), OEHHA found the chemical to be negative in several mutagenicity tests. However, a positive test was reported for the induction of forward mutations in the mouse lymphoma assay. Large doses of methoxychlor decreased locomotor activity and caused tremors. Reproductive effects have been caused by the estrogenic activity of the o-demethylated metabolites of methoxychlor. These metabolites also bind estrogen receptors in animal and human tissues.

OEHHA identified the investigation by Chapin et al. (1997) as the most relevant study for use in developing a PHG for methoxychlor in drinking water. The investigation focused on effects of perinatal methoxychlor exposure on adult rats' nervous, immune, and reproductive system function. Dams were dosed orally at gestation day 14 through postnatal day (pnd) 7 and then pups were directly dosed at pnd 7 through pnd 42 at dosages of 0, 5, 50, and 150 mg/kg-day. Critical effects included a reduction in serum FSH, ovary weight and uterine weight at all dosages. The findings suggested that methoxychlor, as an exogenous estrogenic agent, had interfered with the normal programming of the ovarian-pituitary axis.

Applying the LOAEL of 5 mg/kg/day and an uncertainty factor of 1000 (10 each for inter-species extrapolation, intra-human variability, and LOAEL to NOAEL extrapolation), OEHHA calculated a safe dose of 0.005 mg/kg-day. This in turn was used to derive a PHG of 0.03 mg/L.

Current Evaluation Results

Stoker et al. (1999) investigated the effect of perinatal exposure of methoxychlor on the prostate of adult rat. The study showed that a perinatal dose of 50 mg/kg methoxychlor to the dam only from gestation day 18 to postnatal day 5 resulted in offspring with increased lateral prostate weight and inflammation at 90 days of age.

Welshons et al. (1999) reported increases in adult prostate size in mice from fetal exposure to methoxychlor. Females were dosed from day 11 to day 17 of pregnancy at 20 or 2000 µg/kg maternal body weight per day. Pups were weaned on postnatal day 23. When males reached 8.5 months old (adult), a randomly selected male from each litter was individually housed for 4 weeks to eliminate any effects of having been housed with other males before the selected male was sacrificed for various examinations. Prostatic weights were significantly increased in the 20 and 2000 µg/kg groups.

Table 2.4.1 Effects of Methoxychlor on Prostate Weight

	Prostate (mg)
Control	40.0±3.0
Methoxychlor (20 µg/kg)	64.5±3.7
Methoxychlor (2000 µg/kg)	60.3±4.1

The finding is not surprising as the prostate contains both androgen and estrogen receptors (Kumar et al., 1995) and it has been observed that estrogen can stimulate the growth of the stromal compartment of the prostate (Ekman, 2000). The study also illustrates the irreversible impact of endocrine disruptors during development.

vom Saal et al. (1995) discussed evidence that during fetal life, hormones have marked effects on subsequent behaviors. Male mice are particularly active in urine-marking behavior to indicate their social status. Urine marking was used as the end point to measure the effect of methoxychlor. Females received 0, 1, 10, 100, 1000, or 5000 µg/d from day 11 to day 17 of pregnancy. Two males from each litter were randomly selected when they were 60 days old and housed individually for four weeks to eliminate any effects of having been housed with other males. Urine-marking tests were conducted for one hour in clean cages with the floor lined by a sheet of Whatman No. 2 filter paper. The filter paper was then removed and discrete urine marks (which fluoresce under UV light) deposited on it were counted. The lowest dose (1 µg/day or 20 µg/kg-day based on 0.05 kg maternal weight) of methoxychlor significantly increased urine-marking behavior in male offspring.

Recommendation

OEHHA recommends that a chRD for methoxychlor be developed based on the data from Welshons et al. (1999) and vom Saal et al. (1995). While the exposure period used to demonstrate the significant effect on the prostate or neurobehavior was in the fetal period, OEHHA feels that both the prostate and neurobehavioral data (territorial marking) are applicable for school age children. The human prostate development is biphasic, with much of the growth occurring at puberty. It is small (weighs about 2 g) in childhood and undergoes exponential growth to about 20 g at puberty (Hayward et al., 2000). On the other hand, the process of brain development and maturation continues into adolescence (Rice et al., 2000). These systems remain vulnerable during the K-12 schooling period. Therefore, the Welshons and vom Saal data are an appropriate basis for evaluating hazards at schools.

OEHHA has also considered the appropriateness of using the maternal dose to calculate the chRD. OEHHA finds that methoxychlor crosses the placenta and partitions into the

lipids of milk (OEHHA, 1999). It is likely that the corresponding pup dose is higher on a per kilogram body weight basis. However, the demethylated (phenolic) metabolites rather than methoxychlor were shown to be the active species that displayed the endocrine disruption potential. The polar metabolites would not cross the placenta effectively. Additionally, methoxychlor that crosses the placenta would not be metabolized effectively by the pup whose P-450 enzymes are not fully developed. Thus, it would not be too conservative to use the maternal dose in this case to calculate the chRD.

Calculation of the non-cancer chRD for methoxychlor is based on the following equation:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF}} = \frac{20 \mu\text{g/kg-day}}{1000} = 0.02 \mu\text{g/kg-day}$$

Where,

LOAEL= Lowest-observed-adverse-effect-level based on Welshons et al. (1999) and vom Saal et al. (1995)

UF= Uncertainty factor of 1000 (10 for inter-species extrapolation, 10 for intra-human variability, and 10 for LOAEL to NOAEL extrapolation)

Accordingly, OEHHA is proposing a non-cancer chRD of 0.02 $\mu\text{g/kg-day}$ for methoxychlor to be used in school-site risk assessment.

2.5 Nickel

Nickel, an important industrial metal, comprises 0.008 percent of the earth's crust (Duke, 1980 as cited in ATSDR, 1997). The production, use, and disposal of nickel have led to its mobilization in the environment and human exposure. Nickel is used in aircraft frames, jet engines, gas turbines, and turbosuperchargers, boats, hulls, propellers, and pumps (OEHHA, 2001). Nickel alloys are used in pumps and pipes to resist corrosion in petro-chemical industries. In addition, nickel is used in making coins and jewelry; as catalysts; and in magnets, batteries, and color pigment. Nationwide in 2000, 651,000 pounds of nickel were emitted into the air (with nickel plating operations as a major source of emission), 30,000 pounds were discharged into surface water, 17,000 pounds were injected underground, 2,032,000 pounds were disposed of onsite, and 8,700,000 pounds were disposed of offsite (U.S. EPA, TRI2000).

Nickel was selected for further evaluation pursuant to Health and Safety Code Section 901(g) because it meets both criteria for selection identified in OEHHA's 2002 report (OEHHA, 2002):

- DTSC reported the presence of nickel at two percent of the potential school sites evaluated to date. ARB reported its occurrence in California air (OEHHA, 2002). In addition, U.S. EPA and ARB/DHS have deemed nickel as a chemical of interest in their NHEXAS and Portable Classroom Study, respectively.
- OEHHA (2001) found a number of studies concerning the reproductive effects of nickel compounds. Nickel also adversely affected the immune functions in animals. The administration of nickel to rats increased the concentration of the metal in the hypothalamus and pituitary and inhibited prolactin secretion.

Pertinent Guidance Values

U.S. EPA RfD: 0.02 mg/kg-day

U.S. EPA's RfD is based primarily on the results of a two-year feeding study using rats given 0, 100, 1000 or 2500 ppm nickel (estimated as 0, 5, 50 and 125 mg Ni/kg bw) in the diet (Ambrose et al. 1976). In the 1000 and 2500 ppm groups (50 and 125 mg Ni/kg bw, respectively) body weights were significantly decreased compared with controls and the females had significantly higher heart-to-body weight ratios and lower liver-to-body weight ratios than controls. Since no significant effects were reported at 100 ppm (5 mg Ni/kg bw), this dose was a NOAEL. In this study, two-year survival was poor, particularly in control rats of both sexes (44 of 50 died), raising some concern about the interpretation of the results of this study. A subchronic study conducted by American Biogenics Corp. (ABC, 1986) also found 5 mg/kg-day to be a NOAEL, which supported the Ambrose et al. (1976) chronic NOAEL of 5 mg/kg-day.

An uncertainty factor (UF) of 300 (10 for interspecies extrapolation, 10 to protect sensitive populations, and 3 to account for inadequacies in the reproductive studies) was applied to the NOAEL of 5 mg/kg-day to compute an RfD of 0.02 mg/kg-day.

OEHHA PHG: 11.8 µg/L (a safe dose of 1.1×10^{-3} mg/kg-day)

OEHHA (2001) established a Public Health Goal (PHG) for nickel in drinking water that is based on three reproductive studies in rats (Smith et al., 1993; Springborn Laboratories, 2000a, b). In the Smith study 61-64 day old female rats (at puberty) were dosed at 0, 1.3, 6.8, or 31.6 mg/kg-day for 11 weeks prior to mating and then continuously during two sequential gestation and lactation periods. Breeder males were unexposed. The proportion of dead pups per litter was significantly increased in the 31.6 mg/kg-day group in both breedings and also in the 1.3 mg/kg-day group in the second breeding. Thus, 1.3 mg/kg-day was considered the LOAEL for this study.

The first Springborn report (Springborn Laboratories, 2000a) summarized a one-generation reproduction range-finding study in rats. 102 day-old animals (at sexual maturity) were dosed at 0, 10, 20, 30, 50, or 75 mg nickel sulfate hexahydrate/kg-day for two weeks prior to mating. OEHHA observed significant pup mortality at the lowest dose (10 mg nickel sulfate hexahydrate/kg-day or equivalent to 2.2 mg nickel/kg-day) and deemed it as the LOAEL for this study.

Following the range-finding study, Springborn Laboratories (2000b) conducted a two-generation reproduction study. Nickel sulfate hexahydrate was administered at 0, 1, 2.5, 5, or 10 mg/kg-day. Dosing of the F₀ animals began at 10 weeks prior to mating and dosing of the F₁ rats began on postpartum day 22 (just after weaning, at a young age). For both generations, daily dosing of the dams was continued until lactation day 21. In this two-generation study, no adverse effects were observed even at the highest dose, 10 mg/kg-day (2.2 mg nickel/kg-day).

In reviewing these three studies in totality, OEHHA concluded that the 1.1 mg nickel/kg-day (5 mg nickel sulfate hexahydrate/kg-day) dose in the two-generation study was the appropriate NOAEL for use in calculating the PHG. It represents the highest NOAEL that is lower than the LOAEL from either the Smith, or Springborn range-finding, study.

OEHHA applied this NOAEL in conjunction with an uncertainty factor of 1000 (10 for inter-species extrapolation, 10 to account for human variability, and 10 for database deficiencies for carcinogenic effect via oral route) for calculating a safe dose of 1.1 µg/kg-day. The safe dose was in turn used to derive the PHG.

Current Evaluation Results

Nickel has been cited in the PHG report as having adverse effects on several sensitive organ systems that are undergoing development in school children (OEHHA, 2001). For

example, it affected the hypothalamus-pituitary axis and inhibited prolactin secretion; it reduced a variety of T-lymphocytes and natural killer cell-mediated immune functions; and it impacted the reproductive system and viability of offspring. Against this background, OEHHA targeted the literature search using the criteria outlined in the Introduction Section. We came up with a list of 18 references; all of which were qualitative studies and thus not usable in the context of the current task.

OEHHA modified its strategy, which stipulated a broad-based literature search. A total of 18,410 references were compiled. These references and their abstracts were put into a Procite database. The database, in turn, was queried in an attempt to identify quantitative studies with nickel doses in the range, or below that, of 1.1 mg/kg-day. The purpose is to run another check that we have identified the "lowest" LOAEL or NOAEL during the PHG review. The results support that conclusion.

Recommendation

The current broad-based literature search has not identified data to suggest that the NOAEL should be changed from that used as the basis for the PHG. The PHG NOAEL addresses the reproductive end point that is one of the targeted organ systems for this review, and the exposure time and duration of rats stipulated in the Smith and Springborn studies covers the critical windows for exposure of pre-school and school children. As such, the PHG NOAEL should be used to develop a child-specific RD for use in school-site risk assessment.

OEHHA has considered the appropriateness of using an oral absorption factor for calculating the chRD for nickel. OEHHA noted that human absorption of nickel depends on the dietary matrix (OEHHA 2001). Absorption is significantly higher when water is used as the administration vehicle, compared to when food is used. Alexander et al. (1974) estimated a 40 percent absorption for healthy children on a balanced diet that consisted of milk, cereal, and other food. McNeely et al. (1972), on the other hand, estimated a 1.6 percent absorption for adults on a regular diet (water and food). These data suggest the appropriateness of applying a child protective factor of three to account for the absorption difference between children and adults.

Because a PHG can be based on a cancer or non-cancer endpoint, OEHHA applied a factor of 10 to account for database deficiencies for carcinogenic effect via oral route in deriving a PHG safe dose for nickel. Since a non-cancer chRD by definition addresses the non-cancer endpoint only, OEHHA in this situation has not applied that database deficiency factor in calculating the chRD for nickel.

Calculation of the chRD for nickel is based on the following equation:

$$\text{chRD} = \frac{\text{NOAEL}}{\text{UF} \times \text{CP}} = \frac{1.1 \text{ mg/kg-day}}{100 \times 3} = 3.7 \text{ } \mu\text{g/kg-day}$$

Where,

NOAEL = No-observed-adverse-effect-level from Smith et al., 1993;
Springborn Laboratories, 2000a, b.

UF = Uncertainty factor of 100 (10 for inter-species extrapolation, 10
for human variability).

CP = Child protective factor of 3 to account for the GI absorption
difference between children and adults.

Accordingly, OEHHA is proposing a non-cancer chRD of 3.7 $\mu\text{g}/\text{kg}\text{-day}$ for nickel to be
used in school-site risk assessment.

3. Conclusion

This report summarizes OEHHA's evaluation of cadmium, chlordane, heptachlor (and its metabolite heptachlor epoxide), methoxychlor, and nickel. Based on the evaluation, OEHHA proposes to establish a chRD for each of these chemicals pursuant to the second part of Health and Safety Code Section 901(g). They are listed in Table 3.1 along with other pertinent numerical health criteria.

Table 3.1 Numerical Non-cancer Health Criteria

	OEHHA's Proposed chRD (mg/kg-day)	OEHHA's PHG Safe Dose (mg/kg-day)	U.S. EPA's RfD (mg/kg-day)
Cadmium	1×10^{-5}	1×10^{-5}	5×10^{-4}
Chlordane	3.3×10^{-5}	1×10^{-5}	5×10^{-4}
Heptachlor	3×10^{-5}	1×10^{-4}	5×10^{-4}
Heptachlor epoxide	1.3×10^{-5}	1.3×10^{-5}	1.3×10^{-5}
Methoxychlor	2×10^{-5}	5×10^{-3}	5×10^{-3}
Nickel	3.7×10^{-3}	1.1×10^{-3}	2×10^{-2}

Lennox School District

Response and Comments on the Supplement to the Draft Environmental Impact Statement/ Environmental Impact Report

**LENNOX SCHOOL DISTRICT
10319 Firmona Avenue
Lennox, California 90304**

**RESPONSE AND COMMENTS ON THE
SUPPLEMENT TO THE DRAFT
ENVIRONMENTAL IMPACT STATEMENT/
ENVIRONMENTAL IMPACT REPORT**

**TO: United States Department of Transportation
Federal Aviation Administration**

**City of Los Angeles
Los Angeles World Airports**

DATE: November 6, 2003

PREPARED BY:

**Orbach & Huff LLP
1901 Avenue of the Stars, Suite 575
Los Angeles, CA 90067**

In consultation with:

**The Phylmar Group, Inc.
2342 Manning Avenue
Los Angeles, CA 90064-2208**

**Martin Newson & Associates LLC
501 Santa Monica Boulevard,
Suite 508
Santa Monica, CA 90401**

**Iris Environmental
1615 Broadway, Suite 1003
Oakland, CA 94612**

**Professor Gary W. Evans
Director of Graduate Studies
Cornell University
E306 Martha Van Rensselaer Hall
Ithaca, NY 14853-4401**

**Austin-Foust Associates, Inc.
2020 North Tustin Avenue
Santa Ana, CA 92705**

TABLE OF CONTENTS

	<u>Page</u>
INTRODUCTION	2
DISCUSSION	3
PART ONE - THE ENVIRONMENTAL JUSTICE ANALYSIS OF THE SUPPLEMENT TO THE DRAFT EIS/EIR VIOLATES CEQA	3
1. The SEIS/EIR Is Bound By Environmental Justice Considerations	3
2. Alternative D Unfairly and Disproportionately Burdens Minority Schools	3
a. Significant impact of increased noise on education in Lennox School District schools	4
b. Significant impacts of increased noise on students, teachers, staff and administration	5
c. Significant impacts of increased pollution on students, teachers, staff and administration	6
3. The SEIS/EIR Violates CEQA By Failing to Consider Alternatives that Equitably Distributes Burden Among Populations	8
4. The SEIS/EIR Violates CEQA By Failing to Provide Mitigation Measures for the Significant Environmental Justice Impacts	9
PART TWO - THE SEIS/EIR IMPROPERLY RELIES UPON AND OVER ESTIMATES THE EFFECT OF THE SETTLEMENT AGREEMENT	10
1. The SEIS/EIR Fails to Consider All Possible Surcharges on the Avigation Easements .	11
2. The Impacts of the Alternate D Will Constitute a Surcharge on the Avigation Easements	12
3. The Existence of the Settlement Agreement is Irrelevant to Whether LAWA Must Comply With CEQA	13

PART THREE - THE NOISE ANALYSIS OF THE SEIS/EIR IS INADEQUATE 15

1. The SEIS/EIR Under-Predicts Noise Impacts to Lennox School District Facilities By Omission 15
2. The SEIS/EIR Under-Predicts Noise Impacts on Lennox School District Facilities by Relying on Noise Modeling Results Which Are Acknowledged Within the Report to under-Predict Actual Aircraft Noise Levels 15
3. The “Single Event” Noise Analysis Presented in the SEIS/EIR is Incomplete 16
4. The Limited ‘Single Event’ Noise Analysis Presented in the SEIS/EIR Substantially Under-Predicts Impacts to Lennox School District Facilities in a Number of Ways 16
 - a. The indoor classroom L_{max} thresholds are set too high 16
 - b. Classroom interior noise levels based upon assumed 29 dBA out-to-in aircraft noise reduction do not adequately protect a large enough proportion of classroom users in the Lennox School District 17
 - c. The SEIS/EIR’s proposed 84 dBA L_{max} outdoor single event noise threshold is too high to assess single event noise impact upon classrooms, leading to a severe under-reporting of existing and future noise impacts 18
 - d. The main body of the SEIS/EIR should consider significantly increased cumulative duration to excessive noise levels as a significant noise impact 19
5. The Project Alternatives Included in the EIS/EIR Do Not Appear to Satisfy CEQA or NEPA Requirements 20
6. The Analysis of Temporary Aircraft Noise Impacts Is Inadequate 21
7. Inadequate/Mislabeled Data in Supplemental Aircraft Noise Technical Report 21
8. Specific Noise Mitigation Measures for Lennox School District Facilities Are Not Identified in the SEIS/EIR 21
9. The SEIS/EIR’s Analysis of the Health Effects of Noise on Students Is Flawed 22
 - a. The SEIS/EIR improperly relies on a flawed FICON document 22
 - b. The SEIS/EIR ignores the scientifically confirmed and well-established link between noise exposure and children’s learning 23

- c. The SEIS/EIR entirely neglects the substantiated link between noise and other adverse learning and health effects on children 24
- 10. The SEIS/EIR's Proposed Noise Study is Inadequate 25
 - a. LAWA may not postpone its proposed noise study absent a commitment by LAWA to mitigate 25
 - b. A deferred noise analysis is inappropriate 26
 - c. Failure to conduct a study prior to publishing the SEIS/EIR is against public policy 27
 - d. The proposed noise study must meet stringent scientific standards to be valid ... 27

PART FOUR - THE EMISSIONS, MODELING, MITIGATION MEASURES AND HEALTH IMPACT ANALYSIS OF THE SEIS/EIR IS INADEQUATE 30

- 1. The Emissions Estimations In The SEIS/EIR Violate CEQA 31
 - a. Jet aircraft emission estimates may be underestimated as the methodology used to estimate particulate emissions from jet aircraft is unclear and may be flawed 31
 - b. Potentially significant evaporative emissions of toxic air contaminants resulting from the storage and handling of organic liquids may not have been quantified 32
- 2. The Modeling Approach of the EIS/EIR Violates CEQA 32
 - a. The extent to which emissions from motor vehicles traveling the I-405 and I-105 interstate highways have been included in the air quality analysis is unclear. Emissions of carbon monoxide, toxic air contaminants, particulate matter, and ozone precursors from these sources may be underestimated. Airborne concentrations of these chemicals at locations downwind from the freeways (e.g., community of Lennox) may be underestimated accordingly 33
 - b. The extent to which "sound walls" and other structures have been considered in the dispersion modeling of carbon monoxide and toxic air contaminants is unclear. Airborne considerations of carbon monoxide and toxic air contaminants at locations where "downwash" and "cavity" effects occur may be underestimated 34

c.	The methodology used to estimate plume rise from jet aircraft is questionable and requires further justification	35
d.	The assumption that building downwash is negligible requires further justification	36
e.	The meteorological data set used is inadequate relative to EPA recommendations	36
f.	Atmospheric conversion of sulfur dioxide to sulfate may be significant and is not addressed	37
g.	Secondary formation of toxic air pollutants may be significant and is not addressed	37
h.	The exclusion of deposition effects from the multipath risk analysis is not justified	38
3.	The Mitigation Measures Proposed By The SEIS/EIR Violate CEQA	39
a.	The mitigation measures proposed in the SEIS/EIR have not met all requirements outlined in the SCAQMD CEQA Handbook	39
b.	Mitigation measures, except those specific to construction activities, should be applied towards the No Action/No Project alternative in addition to Alternatives A, B, C, and D	40
4.	The Health Risk Analysis of the EIS/EIR Violate CEQA	41
a.	Alternative D with mitigation may result in a potentially significant increase in cancer risk (over baseline) to schoolchildren and/or residents in and around Lennox	41
b.	Incremental cancer and noncancer risks in the area northeast of the I-105/I-405 Interchange may be underestimated under all project alternatives	42
c.	Estimated cumulative cancer risks to school children have been underestimated due to underestimates in the total number of years children spend in school	42
d.	Significant flaws in the methods used to calculate cumulative cancer risks and noncancer hazards undermine the conclusions of the EIS/EIR and obscure actual health risks posed by the various alternatives	43

e.	The basis for significance threshold for noncancer health effects is unclear and five times greater than the threshold typically used by regulatory agencies	44
f.	The EIS/EIR fails to consider and evaluate the potential health impacts associated with exposure to lead	45
g.	Excluding particulate emissions from jet aircraft from the quantitative risk evaluation could significantly underestimate the potential for noncancer health impacts	46
h.	Absolute cancer and noncancer risks are not presented in the EIS/EIR	48
i.	The EIS/EIR does not consider child-specific noncancer toxicity criteria which have been proposed by the State of California and are intended for use in the risk assessment of California school sites. Noncancer health risks to school children may be underestimated accordingly	48
j.	Use of 1996 as basis for determining project significance is not explained and seems illogical	49
k.	Methodology for establishment of baseline (1996) impacts is poorly defined and highly suspect. All determinations of significance of Alternative D through comparison to 1996 baseline impacts are therefore questionable	49
l.	Alternative D post-mitigation incremental cancer risk to adult residents may be greater than 10 per million individuals	50
m.	Statement that acrolein noncancer risks are substantially overestimated in the EIS/EIR analysis is not supported by the arguments presented	50
n.	Use of different receptor/grid spacing when calculating pre- and post-mitigation impacts prevents assessment of mitigation effectiveness	51
PART FIVE - THE TRAFFIC IMPACT ANALYSIS IS INADEQUATE		51
1.	The Analysis of the Impacts of the Lennox Interchange is Inadequate	52
a.	Street closures may affect children's walk-to-school routes and create safety concerns for children walking to and from school	52
b.	Configuration of entrance and exit freeway ramps will necessitate relocation of a Lennox School District preschool	52
c.	The construction impacts of the Lennox Interchange must be examined	52

2. Traffic Impacts of Alternative D on the Lennox School District Are Not Properly Addressed 52

 a. Impacts of freeway avoidance traffic on Lennox School District are inadequately addressed 53

 b. Construction impacts on traffic in Lennox are inadequately addressed 53

 c. Impacts to Lennox associated with phasing of transportation improvements are inadequately addressed 53

PART SIX - THE ENROLLMENT IMPACT ANALYSIS IS INADEQUATE 53

PART SEVEN - THE SUBSTANTIAL SHIFT IN PROJECT OBJECTIVES REQUIRES LAWA TO EXAMINE AN ADEQUATE RANGE OF PROJECT ALTERNATIVES 54

PART EIGHT -THE EIS/EIR VIOLATES CEQA READABILITY REQUIREMENTS 55

 a. Original EIS/EIR 55

 b. Addition of Supplement to the EIS/EIR 56

CONCLUSION 56

INTRODUCTION

On September 21, 2001, the Lennox School District submitted its Response to the original Los Angeles International Airport ("LAX") Draft Environmental Impact Statement/Environmental Impact Report ("Original EIS/EIR"). The Lennox School District now respectfully submits its Response to the Supplement to the Draft LAX Environmental Impact Statement/Environmental Impact Report ("SEIS/EIR") prepared by the City of Los Angeles, Los Angeles World Airports ("LAWA") and the Federal Aviation Administration. (The Original EIS/EIR and SEIS/EIR are referred to collectively as "EIS/EIR".)

Pursuant to applicable provisions of the California Environmental Quality Act ("CEQA") and the National Environmental Policy Act ("NEPA"), due to its proximity to LAX and the significant environmental impacts LAX has upon Lennox schools, the Lennox School District is an interested party with whom LAWA must consult regarding the SEIS/EIR. (14 *California Code of Regulations* § 15086(a)(4).) Accordingly, the Lennox School District reviewed and analyzed the SEIS/EIR as well as retained qualified experts in the fields of aircraft noise assessment, the effects of noise on human health, behavior and learning, air emissions, regulation and planning, human health risk assessment, traffic engineering and planning, public policy, and environmental and real property law. The work product of these experts is incorporated in the body of this Response.

Although the Lennox School District has undertaken the task of providing this Response, it believes it to be procedurally incorrect and financially unfair for a school district of extremely encumbered financial resources to be burdened with the costs of conducting the initial research and analysis required to be in the SEIS/EIR but omitted.

To the extent new facts and issues are raised in the SEIS/EIR, the Lennox School District provides its response below. To the extent that the SEIS/EIR relies upon or is consistent with the Original EIS/EIR, the Lennox School District incorporates its September 21, 2001 Response and Comments by reference herein. This Response also incorporates the exhibits from the September 21, 2001 Response, and continues numbering the exhibits from that document.

Based upon its review and analysis of the Original EIS/EIR and the SEIS/EIR, the Lennox School District respectfully submits the EIS/EIR fails to satisfy the requirements of either CEQA or NEPA. Accordingly, the Lennox School District respectfully requests LAWA substantially revise its EIS/EIR to: (1) include additional alternatives that address LAWA's new paramount safety and security objectives; (2) specifically address the impacts of the Alternative D discussed herein, as well as the other alternatives contained in the Original EIS/EIR; and (3) provide for proposed mitigation at Lennox School District schools for the benefit of the disproportionately affected children in attendance.

DISCUSSION

PART ONE

THE ENVIRONMENTAL JUSTICE ANALYSIS OF THE SUPPLEMENT TO THE DRAFT EIS/EIR VIOLATES CEQA

All of the alternatives presented by LAWA in its EIS/EIR, including Alternative D presented in the SEIS/EIR, disproportionately impact minorities. The students of the Lennox School District receive an unfair share of the burdens of Alternative D, including educational and health impairments.

1. The SEIS/EIR Is Bound by Environmental Justice Considerations.

LAWA is mandated by federal and state law to identify and address environmental justice issues in its environmental review. *Executive Order 12898* requires that each federal agency "make achieving environmental justice part of its mission by identifying and addressing, as appropriate, disproportionately high and adverse health or environmental effects of its programs, policies, and activities on minority populations and low-income populations." ("Federal Actions to Address Environmental Justice in Minority Populations and Low-Income Populations," *Executive Order 12898*, February 11, 1994, Exhibit 15.)

State law similarly requires consideration of environmental justice issues in environmental impact reports. (*California Public Resources Code* § 71110 *et seq.*) The California Environmental Protection Agency is obligated to "[p]romote enforcement of all health and environmental statutes within its jurisdiction in a manner that ensures the fair treatment of people of all races, cultures, and income levels, including minority populations and low-income populations of the state." (*California Public Resources Code* § 71110(b).)

Thus, the SEIS/EIR must (1) identify disproportionate, adverse environmental and health effects on minority and low income populations and (2) present mitigation measures to alleviate the unfair effects of its project alternatives upon minority and low income populations.

2. Alternative D Unfairly and Disproportionately Burdens Minority Schools.

The Southern California Association of Governments concluded in its 2001 Regional Transportation Plan, ". . . limiting further expansion of LAX is the best possible Plan outcome from an environmental justice perspective. This is due to the relatively high concentration of low-income and minority populations in the vicinity of LAX." The SEIS/EIR admits the "Effects on public schools associated with aircraft noise exposure would fall on schools that are located predominantly within minority and/or low-income communities . . ." (SEIS/EIR, *Environmental Justice*, Section 4.4.3, p. 4-324.)

The Lennox School District is primarily a minority, low-income district. (Original EIS/EIR, *Environmental Justice Technical Report*, Figure 1 and 2, Table 3.) The student population of Lennox School District is 95.6% Latino. (Education Data Partnership ("Ed-Data"), "Fiscal, Demographic, and Performance Data on California's K-12 Schools,"

<http://www.ed-data.k12.ca.us>, Exhibit 16.) According to the 2000 United States census, the Lennox community is 89.8% Latino, 4.1% African American and 3.5% White Non-Hispanic. (United States Census Bureau, <http://factfinder.census.gov>.) The median annual household income is \$28,273 in Lennox. Over 30% of Lennox families are below the poverty line. (*Id.*) More than half of Lennox families are below 150% of the poverty line. (*Id.*) The United States Secretary of Labor has indicated that the Lennox area has one of the highest unemployment levels of the nation. (*Lennox Demographic Information*, Original EIS/EIR Response Exhibit 1.) An average of 95% of students in the Lennox School District are eligible for free or reduced lunches. (*Id.*)

Given the acknowledged burdens placed on Lennox School District schools by Alternative D, options that address the environmental justice impacts should be set forth in the SEIS/EIR.

a. Significant impacts of increased noise on education in Lennox School District schools.

As with the alternatives proposed in the Original EIS/EIR, Alternative D would have a significant adverse impact on the education of students in the Lennox School District. Table S17 of the *Supplemental Aircraft Noise Technical Report* of the SEIS/EIR presents data which provides an indication of the time that the increased airplane overflights under Alternative D will take out of each school day. When considering these numbers, it is important to note that, not only does the interruption lasts at least six seconds (SEIS/EIR, *Noise*, Section 4.1.6.1.5.4.2, p. 4-66), but there is anticipation time as the deafening noise immediately approaches, as well as time spent settling back into instruction after the disruption has receded.

For example, Table S17 suggests Felton Elementary School will lose a total of 45.3 minutes of instructional time each day once Alternative D is implemented. What real impact will this 45.3 minutes have on actual instruction? Approximately 151 times per day, instruction, reading and/or test taking will be stopped or interrupted in the classrooms at this school.¹

Moreover, Buford Elementary School will suffer from an unimaginable 141 interruptions of instruction per day - - over 17 per hour. Children in classes will have to consistently disengage and reengage to classroom instruction, or will simply fail to hear the teacher, every few minutes during each and every class, every day of school. This is, of course, a conservative extrapolation - - the actual number of classroom interruptions is probably far higher. This is also an increase over the baseline. These noise interference numbers are substantially similar to those suggested by Table S31, *Supplemental Aircraft Noise Technical Report*, Section 6.2.2, p. 151.

¹ Assuming overflights occur at a constant rate over a 24 hour day (which, of course, they do not - rather they occur more frequently during the time of instruction): 45.3 minutes = 2718 seconds; 2718 seconds divided by 6 second intervals = 453 occurrences; 453 occurrences divided by 24 hours = 18.8 occurrences per hour; 8 hours of instruction during the day = 151 occurrences per day during the time of instruction.

Furthermore, most students in Lennox schools speak English as a second language. A total of 71.2% of the students in the Lennox School District are "English Learner" students, who are not proficient in English. (Education Data Partnership ("Ed-Data"), "Fiscal, Demographic, and Performance Data on California's K-12 Schools," *supra.*) In fact, 80.3% of students at Felton Elementary School and 74% of the students of Buford Elementary School do not speak English as their first language. (*Id.*) The numerous noise interruptions are particularly debilitating to these students. This fact is not addressed in the SEIS/EIR.

b. Significant impacts of increased noise on students, teachers, staff and administration.

As noted by the World Health Organization, noise interference with speech comprehension results in a large number of personal disabilities, handicaps and behavioral changes. Children in the process of language and reading acquisition are noted to be particularly vulnerable. Problems with behavior, concentration, fatigue, uncertainty and lack of self-confidence, irritation, misunderstandings and a decrease in work capacity have been reported by researchers. (World Health Organization, *Environmental Health Information, Guidelines for Community Noise*, "Adverse Health Effects of Noise," Section 3, April 2001, Original EIS/EIR Response Exhibit 2.)

A study conducted in 1976 in Highline School District looked at the relationship between school test scores for school grades 3-7 and 5-10 for children attending schools exposed to high levels of aircraft noise and other children attending quiet schools. (Maser, A. L., Sorensen, P.H., Kryter, K.D., and Lukas, J.S. *Effects of Intrusive Noise on Classroom Behavior: Data From a Successful Lawsuit*. West. Psychol. Assoc. San Francisco. April 1978, Original EIS/EIR Response Exhibit 3.) While high academic-aptitude students in schools exposed to aircraft noise scored as well in standardized tests as their counter-parts in quiet schools, middle and especially low academic-aptitude students in noisy schools showed progressive deterioration in tests with continued school attendance relative to the students of equal aptitude in quiet schools. (*Id.*)

A study of the impact of various levels of freeway noise on reading test scores highlighted the cumulative adverse effect of noise exposure on school children. (Lukas, J.S., DuPree, R.B. and Swing, J.W. *Effects Of Noise On Academic Achievement And Classroom Behavior*. FHWA/CA/DOHS-81/01 Office of Noise Control, California Dept. Of Health Services, Sacramento. 1981, Exhibit 17.) An apparent degradation in reading achievement with classroom noise that was noted for third-graders, was accelerated by the sixth grade. (*Id.*)

Other research has demonstrated the link between chronic exposure to aircraft noise and many adverse effects including learning, motivational deficits, a significant decrease in total quality of life, increase in psychophysiological stress and susceptibility to helplessness. (Gary Evans and Lorraine Maxwell, "Chronic Noise Exposure and Reading Deficits. The Mediating Effects of Language Acquisition." *Environment and Behavior*, Vol. 29 No. 5, September 1997 [learning deficits], Original EIS/EIR Response Exhibit 4; Cohen S., Krantz, D.S., Evans G.W., Stokols D., and Kelly S., "Aircraft noise and children: Longitudinal and cross-sectional evidence on adaptation to noise and the effectiveness of noise abatement." *J. Pers. Soc. Psychol.* 40: 331-345, 1981 [learning deficits], Exhibit 18; Bullinger, M., Hygge, S., Evans, G.W., Meis, M. and von Mackensen, S., "The Psychological Cost of Aircraft Noise for Children," *Zentralblatt fur*

Hygiene und Umweltmedizin, 202:127-138, 1977 [quality of life decrease], Original EIS/EIR Response Exhibit 5; Gary W. Evans, Monika Bullinger and Staffan Hygge, "Chronic Noise Exposure and Physiological Response: A Prospective Study of Children Living Under Environmental Stress." *Psychological Science*, Vol. 9, No. 1, January 1998 [psychophysiological stress], Original EIS/EIR Response Exhibit 6; World Health Organization, *Guidelines, supra*. [helplessness].)

A 1980 study showed elevated blood pressure of children attending schools under the LAX flight paths compared to children in quiet schools. (Cohen S., Krantz, D.S., Evans G.W. and Stokols D., "Physiological, motivational, and cognitive effects of aircraft noise on children: Moving from the laboratory to the field." *American Psychologist*, 35: 231-243. 1980, Exhibit 19.)

The SEIS/EIR does not suggest that conditions resulting from implementation of Alternative D will result in different circumstances than those discussed in the above-referenced studies. Nevertheless, the SEIS/EIR fails to provide for any remediation for the known impacts of Alternative D on Lennox School District students.

c. Significant impacts of increased pollution on students, teachers, staff and administration.

As noted by the United States Environmental Protection Agency ("USEPA"), exposure to ambient criteria and toxic pollutants resulting from anthropogenic emissions can result in a wide variety of health impacts. (USEPA, *The Benefits and Costs of the Clean Air Act, 1970 to 1990*. Prepared for U.S. Congress, October 1997, Original EIS/EIR Response Exhibit 7.) Short-term health impacts can include eye, nose, and throat irritation; losses in hand-eye coordination (compensatory tracking); vigilance (detection of infrequent events); visual system sensitivity; and increased asthma attacks. (Seinfeld, John H., *Atmospheric Chemistry and Physics of Air Pollution*. New York, John Wiley & Sons, 1986.) Long-term exposures can result in increased mortality, susceptibility to pulmonary bacterial infection, irritation of the alveoli, emphysema, chronic bronchitis, reduced pulmonary function, losses in IQ, and cancer. (*Id.* and USEPA, *Benefits, supra*.)

Furthermore, there is good reason to believe that children could be more vulnerable to these effects. Because of growing concerns regarding children's increased susceptibility to environmental contaminants, the California Legislature passed the Children's Environmental Health Protection Act (SB 25), which requires the California Environmental Protection Agency ("Cal/EPA") to specifically consider children in setting Ambient Air Quality Standards and developing criteria for Toxic Air Contaminants ("TACs"). The law will require Cal/EPA to specifically evaluate available information on children's increased susceptibility to each of the TACs, and develop a list of up to five TACs that potentially have disproportionate impacts on infants and children.

As stated by Cal/EPA, children are considered to be at increased risk because of the rapid growth and development of their nervous, immune and reproductive systems, and because their organs and tissues are rapidly maturing. (Cal/EPA, *Air Pollution and Children's Health*. Fact Sheet by Office of Environmental Health Hazard Assessment, March 2001, Original EIS/EIR

Response Exhibit 8.) In addition, children experience greater exposure to ambient pollutants relative to their body weight, and children's specific activity patterns may contribute to an increased exposure to toxicants resulting from increased exercise and sporting activities. (*Id.*) Asthma has also been identified as a major problem in children, and some of the chemical emissions from LAX have

been identified by Cal/EPA as resulting in an exacerbation of asthma (e.g., formaldehyde and acrolein). (*Id.*)

Furthermore, recent studies suggest that particulate matter ("PM") may exacerbate asthma and cause coughs and other respiratory symptoms in children. (*Id.*) Recent studies also suggest that prolonged exposure to PM may also affect the growth and functioning of children's lungs. (*Id.*) Researchers found that as children grow up in smoggier areas, there is a notable lag in lung function growth. (*Id.*)

In April 2000, the South Coast Air Quality Management District ("SCAQMD") determined that Lennox had the highest concentrations of pollution of all communities neighboring LAX. (SCAQMD, *Air Monitoring Study in the Area of Los Angeles International Airport*, April 2000, Original EIS/EIR Response Exhibit 9.) SCAQMD conducted testing for particulate matter ("PM") and volatile organic compounds ("VOCs") at fourteen sites around LAX. (*Id.*) SCAQMD found that the concentrations of these pollutants were highest on the east side of the airport, particularly at Felton School in Lennox. (*Id.*) As stated in the SCAQMD report:

"Samples collected in the initial study both north and south of the airport typically showed lower concentrations of VOCs than did samples collected east of LAX. This trend held for all mobile source related compounds except benzene, for which the areas east and south of the airport showed comparable values." (*Id.* at p. 11.)

The report goes on to state:

"Using benzene and 1,3 butadiene as the indicators of mobile source activity, clear trends in the west-to-east data emerge. Background sites to the north and south of LAX showed lower levels of VOCs than did sampling locations to the east of these sites. The background sites, on average, were also consistent with respect to the levels of contaminants found. VOC levels were elevated at all locations on the east side of Aviation Blvd. Levels were typically 2 to 3 times higher on average than they were at background locations." (*Id.* at p. 12.)

This pollution has a direct correlation to levels of respiratory illness in Lennox School District students. In fact, UCLA doctors conducting the UCLA Health Fair in Lennox have indicated that a higher percentage of children in Lennox have asthma and other respiratory ailments than in any other Los Angeles area community the Health Fair has visited.

SCAQMD found a strong correlation between airport activity and the pollutant levels found in Lennox. (*Id.*) Alternative D will only exacerbate these problems.

Because of the anticipated environmental and related health impact of noise and pollution on the schools, students could potentially fall behind in their schooling, one class grade or more. Several students could have an impaired ability to retain information as a result of the impact. These students may not be able to grasp as much as other students and would not be able to process more advanced concepts taught in high school that build upon what they were supposed to, but did not, learn in elementary school. More children would have asthma and allergies than they would without the implementation of Alternative D. Children may also have an increased risk of heart attacks and death.

Children in Lennox School District schools may have permanent learning disabilities that limit their career choices and quality of life. Furthermore, they may have shorter lifespans and worse general physical health than other children at other non-impact schools. Lennox School District students may have lifelong psychological weaknesses that would affect every aspect of their lives.

These adverse health impacts are real. These are the impacts that will disproportionately and significantly affect the minority, low- income community of Lennox.

3. The SEIS/EIR Violates CEQA by Failing to Consider Alternatives that Equitably Distributes Burden Among Populations.

Because of the significant and unmitigatable impact of all of the proposed alternatives, including Alternative D, on minority and low-income communities, other alternatives must be explored.

California *Public Resources Code* § 21002 states, in pertinent part:

“The Legislature finds and declares that it is the policy of the state that public agencies should not approve projects as proposed if there are feasible alternatives or feasible mitigation measures available which would substantially lessen the significant environmental effects of such projects, and that the procedures required by this division are intended to assist public agencies in systematically identifying both the significant effects of proposed projects and the feasible alternatives or feasible mitigation measures which will avoid or substantially lessen such significant effects.”

California law requires the SEIS/EIR to consider feasible alternatives that would substantially lessen the disproportionate and significant environmental effects of the project on minority and low-income communities. LAWA failed to do so.

4. The SEIS/EIR Violates CEQA By Failing to Provide Mitigation Measures for the Significant Environmental Justice Impacts.

The SEIS/EIR is required to mitigate the environmental justice burden imposed by Alternative D to the extent feasible. (*California Public Resources Code* §§ 21002, 21002.1.) The SEIS/EIR, however, fails to describe any mitigation measures to alleviate its impacts on schools. Instead, it proclaims that it will *only* provide mitigation measures in those schools not deemed to be Title 21 compliant. (See *Environmental Justice*, Section 4.4.3.5.1.2, p. 4-329; *Supplemental Aircraft Noise Technical Report*, Section 6.2.3, p. 154.) This rationale is flawed for two reasons: (1) it over-estimates the effect of the Settlement Agreement (See Part Two *infra*); and (2) it fails to address the independent obligations of CEQA.

Feasible mitigation programs exist that would address the noise issues in minority and low income schools. Sound insulation can alleviate noise impacts inside classrooms. Working examples of this are the Moffet Elementary School and Dolores Huerta Elementary School. These schools, built with noise mitigation as a key component, are able to provide a decent learning environment despite its proximity to LAX. Compare aircraft noise above 75 dBA for the 1996 baseline: Moffett Elementary School at .5 minutes and Felton Elementary School at 46.0 minutes. (SEIS/EIR, *Supplemental Aircraft Noise Technical Report*, Table S17.) Furthermore, to the extent that the significant noise impacts in Lennox School District schools are unmitigatable, the SEIS/EIR should address the option of relocating those schools.

Additionally, the Lennox School District has been investigating the acquisition of a large vacant parcel of land near Imperial and Aviation for the Lennox Math, Science & Technology High School Academy. However, Alternative D proposes another use for that particular parcel of land. This parcel would have been ideal for the charter school because Lennox is a highly developed and densely populated community with little available vacant land. If LAWA proceeds with Alternative D, Lennox School District will be forced to find another location for the charter school and most likely incur increased costs for condemnation proceedings, payment of relocations benefits and demolition of existing buildings. The impact on the charter high school should be considered when considering impacts and addressing mitigation.

The same mitigation analysis must be conducted for air quality and other significant impacts of the proposed project upon minority and low-income populations.

To the extent feasible, LAWA is obligated to mitigate its impacts on the Lennox School District. (14 *California Code of Regulations* § 15126.4.) The SEIS/EIR fails to do so. The failure to include such mitigation measures in the body of the SEIS/EIR violates CEQA. (*Id.*) Accordingly, this SEIS/EIR is fatally inadequate and must, before further action is taken, be revised to comply with CEQA.

PART TWO

THE SEIS/EIR IMPROPERLY RELIES UPON AND OVER ESTIMATES THE EFFECT OF THE SETTLEMENT AGREEMENT

The Original EIS/EIR states in one volume:

“In the mid-1970's, the City of Los Angeles ... [settled] a noise lawsuit. Under the terms of the settlements, each school in the public ... systems that had participated in the lawsuit agreed to allow an aviation easement, deeming the school to be compatible with the airport under Title 21.” (Original EIS/EIR, *Land Use*, Section 4.2, pp. 4-95, 4-96.)

Over a thousand pages later, the Original EIS/EIR states:

“One public school in the Lennox Elementary School District would be exposed to outdoor noise levels that would remain significant after mitigation unless acquisition or relocation of the schools is undertaken.” (Original EIS/EIR, *Schools*, Section 4.27, p. 4-1219.)

In a separate volume, the Original EIS/EIR states:

“As presented in Technical Report 1, *Land Use*, eight public schools would be exposed to significantly high levels of noise by 2015 within the Inglewood Unified School District and Lennox Elementary School District. For those impacted schools not already considered compatible pursuant to California Code of Regulations, Title 21, mitigation in the form of sound insulation or acquisition and relocation would be provided.” (Original EIS/EIR, *Schools Technical Report*, Section 17, p. 15.)

The SEIS/EIR picks up on these points when discussing mitigation of noise impacts on schools. (See, for example, *Environmental Justice*, Section 4.4.3.5.1.2, p. 4-329; *Supplemental Aircraft Noise Technical Report*, Section 6.2.3, p. 154.)

Thus, the SEIS/EIR both addresses and dismisses further consideration of the impacts upon Lennox School District schools solely based upon the existence of the 1970's Settlement Agreement. (*Amended Judgment and Final Order in Condemnation*, Original EIS/EIR Response Exhibit 11; the operative “Judgment and Final Order” is actually entitled *Amended Judgment and Final Order in Condemnation*, and referred to herein as “Settlement Agreement.”)

It is apparent LAWA has no intention of providing mitigation in any form to Lennox School District schools as part of Alternative D. As set forth below, this deficient approach (1)

fails to even consider the entirety of the terms of the Settlement Agreement; (2) fails to consider other surcharges which would be caused by an expansion not provided for by the express grant of the avigation easement in the Settlement Agreement; and (3) inappropriately avoids and dismisses a proper CEQA analysis.

1. The SEIS/EIR Fails to Consider All Possible Surcharges on the Avigation Easements.

As with the Original EIS/EIR (Original EIS/EIR, *Land Use*, Section 4.2, p. 4-95, fn. 72.), when discussing the historically high noise levels affecting the Lennox School District, the SEIS/EIR refers to and relies solely upon the Settlement Agreement which granted LAWA an avigation easement over Lennox School District schools. (SEIS/EIR, *Supplemental Aircraft Noise Technical Report*, Section 6.2.3, p. 154.) The SEIS/EIR concludes:

“LAWA has established agreement with most public and a few private schools in the airport environs related to the amount of cumulative noise that may be generated from airport operations over each. Where those cumulative noise levels are exceeded (measured in decibels of CNEL), addition of the facility to the list of sound insulation eligibility may be warranted.” (*Id.*)

This conclusion is incomplete and misstates the Settlement Agreement (discussed further in Part Two Sections 2 and 3 *infra*). The Settlement Agreement provides that the purpose of the air easements granted to LAWA are for “noise, vibrations and fumes” over the schools. (Settlement Agreement, page 3, lines 18-21.) The Settlement Agreement further provides:

“Vibration and fume levels are not quantitatively described for the purpose of the distribution of the air easements but it is agreed that those levels of vibration and fumes which accompany the agreed-to CNEL values shall not be a burden of the easements.” (Settlement Agreement, page 11, lines 1-5.)

In other words, LAWA may only contend that the avigation easement is not surcharged if “levels” of vibration and noise are the same as in 1970. What the Settlement Agreement does not discuss, does not preclude, and leaves open is whether a surcharge may occur when the *frequency* of vibrations and fumes is increased from the frequency of vibrations and fumes occurring in 1970.

Paragraphs 4.a and 7 of the Settlement Agreement make clear it was the intent of the parties not to further burden the avigation easements by an increase or “deviation” in frequency of flight operations over Lennox School District schools. Rather such deviations were only permitted if “temporary and not permanent.” (Settlement Agreement, page 13, line 14.)

2. The Impacts of the Alternate D Will Constitute a Surcharge on the Avigation Easements.

Under California law, the extent of an easement is determined by the terms of its grant. (California *Civil Code* § 806.) As stated by the California Supreme Court, an owner of an easement may not increase the use of the easement in any manner that imposes a new or greater burden on the servient tenement without the consent of the servient owner. (*Colegrove W. Co. v. City of Hollywood* (1907) 151 Cal. 425, 429.) Further, "...it is well settled that 'both parties have the right to insist that so long as the easement is enjoyed it shall remain substantially the same as it was at the time the right accrued, entirely regardless of the question as to the relative benefit and damage that would ensue to the parties by reason of a change in the mode and manner of its enjoyment. [Citation omitted.]'" (*Whalen v. Ruiz* (1953) 40 Cal.2d 294, 302.)

In fact, "California courts have set their faces firmly against ... increases in the burden upon the servient tenement." (*Wall v. Rudolph* (1961) 198 Cal.App.2d 684, 694.) Accordingly, "[t]he requirement that the easement involve only a *limited* use or enjoyment of the servient land is a corollary of the nonpossessory character of the interest. If a conveyance purported to transfer to A an *unlimited* use or enjoyment of [a parcel of land], it would be in effect a conveyance of ownership to A [of the parcel of land], not of an easement." (*Id.*, at p. 697; emphasis in original.)

The avigation easement granted by the Lennox School District to LAWA was based upon criteria which have been far exceeded. For example, the number of take-offs and landings identified in Exhibit F in 1970 (used as two of the three elements to establish the CNEL contours) has dramatically increased as of 2003. In 1970, the total of take-offs and landing events per day was 1,061. (Settlement Agreement, Exhibit F, Figures 6, 7.) The total number of take-offs and landing events per day in 2003 is over 1,700, an increase in flight frequency of over 62%. (Los Angeles World Airports, *Traffic Comparison*, May 28, 2003.) This will increase even further to 2,148 under Alternative D, that is, over 100% more than anticipated by the avigation easement. (SEIS/EIR, *Executive Summary*, Table ES-1.)

Moreover, the avigation easement anticipated an *increase* in aircraft operations at LAX up to 40,000,000 passengers annually. (Settlement Agreement, Exhibit F, paragraph B.) LAX is currently operating at over 51,000,000 passengers annually. (Los Angeles World Airports, *Traffic Comparison*, May 28, 2003.) Alternative D predicts an increase in aircraft operations to accommodate at least 78,900,000 passengers annually, once again, almost 100% more than anticipated by the Settlement Agreement. (SEIS/EIR, *Executive Summary*, Table ES-1.) In addition, the amount and frequency of airplane traffic will also necessarily increase under Alternative D to accommodate the predicted increase in cargo tons per year by 50% over today's traffic alone. (*Id.*)

Perhaps most significant, however, is the *decrease in altitude* of air traffic over Lennox School District schools proposed by Alternative D due to the eastward extension of runway 24L and its direct impact on "levels" of noise, vibration and fumes. (See, SEIS/EIR, *Noise*, Sections 4.1.6.1.5.3 and 4.1.6.1.5.4.2, pp. 4-64 and 4-66, respectively.)

Thus, the increase in *frequency* of air traffic through the aviation easement proposed by Alternative D will constitute a material surcharge upon the easement. This increased frequency results in an increase in not only the number of noise events, but in the number of *vibration* and *fume* events as well.

This burden on the easement will, at the very least, require the Lennox School District's consent, and realistically also require further mitigation in the form of additional sound attenuation measures at each of the affected school sites.

Therefore, the SEIS/EIR must further consider, and LAWA must mitigate, the impact upon the existing or future incompatible land use resulting from implementation of Alternative D, as the Judgment and Final Order will not, as suggested, conclusively control the question given the anticipated substantial surcharge upon the aviation easement and resulting burden to the servient tenement, Lennox School District schools.

3. The Existence of the Settlement Agreement is Irrelevant to Whether LAWA Must Comply With CEQA.

The existence of an aviation easement alone does not render a school "Compatible" under Title 21. Throughout the SEIS/EIR, LAWA implies that those schools which entered into aviation easements with LAWA are automatically deemed "compatible" uses, and therefore do not require mitigation. The regulatory definitions of "compatible" and "incompatible" uses do not support this contention.

The definition of incompatible land uses includes:

"[P]ublic and private schools of standard construction for which an aviation easement for noise has not been acquired by the airport proprietor *or* that do not have adequate acoustic performance to ensure an interior CNEL of 45 dB or less in all classrooms due to aircraft noise." (Emphasis added.) (21 *California Code of Regulations* 5014(b).)

The definition stated in the disjunctive is not of "compatible" land uses, but of "incompatible" land uses. Thus, public schools with an interior CNEL of 45 dB are plainly "incompatible" land uses, with or without an aviation easement. The accepted rules of statutory construction simply do not allow any other interpretation or extrapolation to be made by LAWA.

Under the basic tenets of statutory construction, courts will,

"ascertain the intent of the drafters so as to effectuate the purpose of the law [by] . . . first examin[ing] the words themselves, giving them their usual and ordinary meaning and construing them in context. When statutory language is clear and unambiguous, 'there is no need for construction and courts should not indulge in it.' [Citations omitted.]" (*Esberg v. Union Oil Co.*(2002) Cal.4th 262, 268.)

In this case, the plain meaning of the regulation does not present any ambiguity. The use of the word "or" in a regulation indicates an intention to use it disjunctively so as to designate alternative or separate categories. (*Piet v. U.S.* (1959) 176 F. Supp. 576, 583.)

Therefore, those schools that do not have adequate sound insulation to ensure an interior CNEL of 45 dB or less, are incompatible uses for purposes of Title 21 and *are entitled* to mitigation irrespective of whether LAWA holds avigation easements for those schools.

Even if LAWA successfully maintains Alternative D is not a surcharge on the avigation easement granted by Lennox School District, and, despite the foregoing, is nonetheless "compliant" with Title 21, LAWA must still identify the need for and then provide for the implementation of mitigation measures. Under California law:

"Any one may waive the advantage of a law intended solely for his benefit. But a law established for a public reason cannot be contravened by private agreement." (*California Civil Code* § 3513.)

The California Environmental Quality Act ("CEQA") is a state environmental law applicable to public agency decisions to authorize projects that could have an adverse impact on the environment. The purpose of the CEQA Environmental Impact Report requirement is to provide the information needed to make informed decisions in the selection and authorization of projects. (*California Public Resources Code* §§ 21001(g), 21002, 21061; 14 *California Code of Regulations* § 15121.) Without question, CEQA and its requirements are "established for a public reason." Therefore, under both sound principles of law as well as fundamental considerations of fairness and justice, the existence of the avigation easement (a private agreement between two public agencies) cannot "waive" the requirement of mitigation of the significant impacts upon students and teachers associated with Alternative D.

Thus, appropriate project alternatives, significant impacts and related mitigation measures must be analyzed in the SEIS/EIR. (*California Public Resources Code* §§ 21002.1, 21100.) In this instance, the SEIS/EIR must identify measures that would mitigate the impacts of Alternative D on Lennox School District in general and impacted school facilities in particular. (*Id.*) Without this analysis, the selection process is flawed and an informed decision cannot be made.

The Settlement Agreement between the City of Los Angeles and various school districts does not affect this state mandated analysis. The SEIS/EIR claims that the Settlement Agreement operates to mitigate significant impacts upon schools and students. (*Environmental Justice*, Section 4.4.3.5.1.2, p. 4-329; *Supplemental Aircraft Noise Technical Report*, Section 6.2.3, p. 154; See also, EIS/EIR, *Land Use*, Section 4.2.) This claim is in direct contradiction to the requirements of CEQA (14 *California Code of Regulations* § 15126.4) and *Civil Code* §3513.

CEQA requires LAWA to conduct and publicly disclose its analysis of impacts upon affected schools and of measures that can mitigate those impacts, if any. (*Id.*) Thus, the

SEIS/EIR must be revised to conduct a thorough analysis of impacts upon schools and of measures that can be taken to mitigate those impacts. (*Id.*)

PART THREE

THE NOISE ANALYSIS OF THE SEIS/EIR IS INADEQUATE²

1. The SEIS/EIR Under-predicts Noise Impacts to Lennox School District Facilities by Omission.

There appears to be no specific mention of the following Lennox School District schools within the SEIS/EIR:

- Dolores Huerta Elementary School.
- Lennox Math, Science & Technology High School Academy, located on the Whelan Elementary School campus.
- Felton Preschool, located on the Felton Elementary School campus.

The lack of reference to these schools may be because they are not impacted, but the Lennox School District would request some acknowledgement of the existence of these schools within the Final EIS/EIR to provide reassurance that these schools have not merely been overlooked in the analysis.

In addition, Jefferson Elementary School is not included on Table S31 of the *Supplemental Aircraft Noise Technical Report*, which presents changes in the cumulative duration of classroom noise levels above 55 dBA under the various alternatives. The possibility that this school is not exposed to classroom noise levels above 55 dBA under any alternative seems unlikely given the school's proximity to the airport, its alignment with the southern runways and the inclusion in Table S31 of schools that would be expected to be exposed to lower noise levels due to their greater distance from the runways.

2. The SEIS/EIR Under-Predicts Noise Impacts on Lennox School District Facilities by Relying on Noise Modeling Results Which Are Acknowledged Within the Report to Under-Predict Actual Aircraft Noise Levels.

As discussed in the *Supplemental Aircraft Noise Technical Report* (page 15) the INM used for all noise predictions in the SEIS/EIR under-predicts aircraft noise in comparison to real measured noise levels. The study's under-prediction of noise levels is likely to lead to an under-prediction of the number of schools at which the 2015 aircraft noise levels exceed certain noise

²For the purpose of these comments, the use of the terms "Decibel", "dB" and "dBA" are all intended to mean A-weighted decibels.

thresholds of significance. The Lennox School District recommends that the Final EIS/EIR include detailed analysis of the likely real noise impact upon Lennox School District schools.

3. The "Single Event" Noise Analysis Presented in the SEIS/EIR is Incomplete.

The Lennox School District's comments on the Original EIS/EIR pointed out potential disruption to speech communication within classrooms associated with "single events," i.e., the noise associated with individual aircraft flyovers. The Lennox School District is pleased to see that single events are now considered within the SEIS/EIR. The District remains concerned, however, that the issue of the applicable threshold(s) of significance has not been resolved within the SEIS/EIR.

Mitigation measure MM-LU-4, which incorporates specific noise mitigation measures for schools, is "subject to modification" based upon the results of further study. Details of the proposed 'further study' are not, however, provided for our comment.

4. The Limited 'Single Event' Noise Analysis Presented in the SEIS/EIR Substantially Under-predicts Impacts to Lennox School District Facilities in a Number of Ways.

a. The indoor classroom L_{max} thresholds are set too high.

The *Supplemental Aircraft Noise Technical Report* proposes a 55 dBA L_{max} threshold of significance for teaching classes. According to Page 149 of this report, this threshold was derived from Table 3.3 of a 1992 FICON publication, using a speaker-to-listener distance of 20 feet and assuming a raised voice level. Reference to the FICON 1992 publication shows that the table in question was reproduced from the 1973 EPA publication, "Public Health and Welfare Criteria for Noise," ("EPA Report") as Figure 6.1 of the EPA Report.

The EPA Report qualifies the data in a number of important ways. The qualifications include the following:

- Figure 6.1 published by EPA in 1973 was for an outdoor noise environment. Page 6-7 of the EPA Report states that the data "is not valid to assess the intrusion of the outdoor levels on the reception of speech indoors because of the reverberant build up of sound by reflections from the walls of the room. . . The data in the pertinent literature suggests that, for most instances, a reasonable value for the design of rooms where oral communication is important is somewhere in the range 40-45 dBA."
- Page 6-7 of the EPA Report goes on to state, "Lower noise levels would be required if the talker has imprecise speech (poor articulation) or if the speaker and listener speak different dialects." Considering the fact that (1) the speaker in the classroom is occasionally the student, and (2) the student's first language is often not the same as that of the teacher, these qualifications are

certainly applicable in Lennox School District schools. (See Part One, Section 2, *supra*.)

- Page 6-7 of the EPA Report also states that the data in its Figure 6.1 represents conditions for young adults and that “adequate speech communication with children requires lower noise levels than are required for adults”. This qualification also applies to the Lennox School District schools.
- Pages 6-7 to 6-8 of the EPA Report also state, “Persons with hearing losses require more favorable speech-to-noise ratios than do those with normal hearing.” Given that all pupils will not all have perfect hearing at all times, due in great part, but not exclusively, to frequent childhood ear infections, this qualification is also pertinent. In addition, Lennox School District students reside within the Lennox community and are afflicted with long-term, likely unmitigated exposure to aircraft noise at home, possibly resulting in permanent hearing loss. This potential for permanent hearing loss should also be considered.

The EPA qualifications of the data were not contemplated in the SEIS/EIR analysis. Appropriate consideration of these qualifications would result in a lower threshold for the application in question.

On the above basis, the Lennox School District believes the 55 dBA L_{max} indoor criterion used in the SEIS/EIR to be incorrectly derived. A lower criteria based upon consideration of all relevant factors, including: talker-to-listener distances greater than 20 feet, noise effects in indoor environments, the need for a higher signal-to-noise ratio for children, children’s propensity to temporary hearing loss, and children with limited English proficiency should be utilized by LAWA.

b. Classroom interior noise levels based upon assumed 29 dBA out-to-in aircraft noise reduction do not adequately protect a large enough proportion of classroom users in the Lennox School District.

According to the *Supplemental Aircraft Noise Technical Report*, the 29 dBA out-to-in noise reduction for aircraft noise intrusion to classrooms is the average result of sample measurements conducted at “several schools” by LAWA. (p. 149.) Insufficient details were provided in the SEIS/EIR to assess whether the sampling was applicable to Lennox School District classrooms. Furthermore, since the 29 dBA is an average result, several classrooms in the study must have lower sound attenuation levels. It is therefore likely that sound insulation for some Lennox School District classrooms would be lower than 29 dBA.

Deriving an indoor noise impact threshold using the 29 dBA average would not adequately protect the occupants of those classrooms with worse than average sound isolation. For example, as is common in Southern California, the Lennox School District utilizes 113 portable classrooms. These would not generally be expected to provide such a high level of out-

to-in noise reduction for aircraft noise. The noise threshold for mitigation should be designed to protect actually impacted classrooms, not just the 'average' case.

- c. **The SEIS/EIR's proposed 84 dBA L_{max} outdoor single event noise threshold is too high to assess single event noise impact upon classrooms, leading to a severe under-reporting of existing and future noise impacts.**

The World Health Organization ("WHO") states that for speech to be intelligible when listening to complicated messages, such as in schools, interfering noise should not exceed 35 dBA. (World Health Organization, *Guidelines, supra.*) Assuming the classrooms in question operate with closed windows and doors (which would assume the existence of air-conditioning in the classrooms) and have been provided with sound attenuation to achieve a minimum noise level reduction of 25 dB (as required under the Land Use Compatibility Guidelines of the Federal Aviation Regulations for schools exposed to aircraft noise in the CNEL 65 to 70 range), this would suggest that occurrence of outdoor noise levels exceeding 60 dBA, which is much lower than the 84 dBA threshold, would result in speech interference within classrooms.

Even using the upper limit of the EPA's suggested range (see item 4 a., above) of 45 dBA as being a threshold above which interference with typical speech becomes noticeable indoors, and again assuming 25 dBA out-to-in sound insulation, such a conservative analysis would suggest speech disturbance would be noticeable when outdoor noise levels exceed 70 dBA. Again this is a much lower threshold than 84 dBA.

Table S17 of the *Supplemental Aircraft Noise Technical Report* presents results for time above 75 dBA outdoors. Reviewing the range of thresholds for speech interference discussed above, it is highly likely that aircraft noise levels exceeding 75 dBA at a school result in speech interference within classrooms. (As discussed above, the appropriate threshold is probably lower than 75 dBA.) Table 1 below, presents "time above" data in minutes, projected for the year 2015 unless otherwise indicated, for Lennox School District schools extracted from Table S17 of the *Supplemental Aircraft Noise Technical Report*.

Table 1 - Aircraft Noise Time above 75 dBA in Minutes, for the year 2015 unless otherwise stated.

School	1996	No Project	Alt. A	Alt. B	Alt. C	Alt. D
Felton Elementary School – PBS035	46.0	45.5	31.6	49.4	47.5	45.3
Lennox Middle School – PBS091	8.2	5.2	7.7	41.8	5.2	4.8
Buford Elementary School – PBS019	41.6	38.2	44.7	25.8	42.9	42.3

Moffet Elementary School – PBS102	.5	.7	1.2	30.1	.7	.7
Jefferson Elementary School – PBS055	26.0	28.3	14.1	45.3	26.5	24.8
Whelan Elementary School - PBS123	52.1	51.7	47.0	33.5	56.1	55.0

The results presented in Table 1 suggest that the cumulative duration of speech interference in classrooms per day for all of the above Lennox School District schools is high under nearly every project alternative scenario. Given the amount of speech disturbance levels indicated by the conservative analysis presented above, any further increase in cumulative duration of speech disturbance is of serious and immediate concern. The *Supplemental Aircraft Noise Technical Report's* reliance on analysis using a time above 84 dBA outdoor noise level clearly understates the existing and future aircraft noise disturbance at Lennox School District facilities.

When speech interference occurs in the classroom, students suffer a loss of learning time. Other possible outcomes include students failing to understand important information from the teacher, loss of concentration during study, or interference with standardized testing. (See Part One, Section 2b., *supra*.) The predicted increase in the duration of speech interference in Lennox School District classrooms gives rise to serious noise impacts that do not receive adequate attention in the SEIS/EIR.

Instructional learning also suffers from speech interference that occurs outside the classroom. Schools are required to provide 200 minutes of Physical Education to children for every two-week period. Physical Education does comprise 'actual learning' which is interrupted at an even greater frequency and intensity than in the classroom. In addition, schools are faced with safety issues when children cannot hear teachers over aircraft noise during Physical Education activities.

d. The main body of the SEIS/EIR should consider significantly increased cumulative duration to excessive noise levels as a significant noise impact.

The *Supplemental Aircraft Noise Technical Report* introduces three thresholds of significance for single event impacts upon classrooms (55 dBA L_{max} , 65 dBA L_{max} and 35 dBA L_{eq} (1 hour)). It states, "Each school listed on the tables may, for CEQA purposes, be considered single event impacted if its noise level exceeds any of the three thresholds of significance . . ." (SEIS/EIR, *Supplemental Aircraft Noise Technical Report*, Section 6.2.2, p. 150.) The main body of the SEIS/EIR, however, appears to only consider *new exposure* to levels above these thresholds (as opposed to all levels in excess of these thresholds) as the threshold of significance. This is in clear contrast to the pronouncements in the *Supplemental Aircraft Noise Technical Report*. No justification has been provided in the SEIS/EIR for its failure to acknowledge these impacts.

This can be illustrated by the example of Felton Elementary School. According to the *Supplemental Aircraft Noise Technical Report*, the classrooms at this school are exposed to instantaneous indoor noise levels exceeding 55 dBA for a cumulative duration of 2.4 minutes per day based upon the 1996 baseline. Under Alternative D, in 2015, this cumulative duration would increase to 6.8 minutes per day. This is a 283% increase in cumulative daily exposure to classroom noise levels above 55 dBA, yet the main body of the SEIS/EIR, which uses *new exposure* to any event louder than 55 dBA levels as the threshold of impact for single events, fails to acknowledge a noise impact at this school.

Out of the six Lennox School District schools considered in the SEIS/EIR, the report only identifies single event noise impact to two schools. These impacted schools are Lennox Middle School (new exposure to an L_{eq} (1 hour) level above 35 dBA under Alternative B) and Moffett Elementary (new exposure to maximum classroom noise levels above 55 dBA under Alternative A and new exposure to an L_{eq} (1 hour) level above 35 dBA under Alternative B).

It should be noted, however, that the remaining four Lennox School District schools considered in the SEIS/EIR - Buford Elementary School, Felton Elementary School, Jefferson Elementary School and Whelan Elementary School - are all already above at least one of the report's three thresholds under the 1996 baseline. Felton Elementary School is above all three thresholds at 1996 baseline levels. Given the existing (1996) high aircraft noise exposure at these schools, any increase in cumulative duration of speech disturbance is considered troubling and use of the *newly exposed* requirement leads to a failure to consider such impact.

Given the substantial amount of existing speech disturbance, any increase in cumulative duration of speech disturbance is considered troubling and again, use of the *newly exposed* requirement leads to an understatement of the noise impact associated with all of the project alternatives considered.

5. The Project Alternatives Included in the EIS/EIR Do Not Appear to Satisfy CEQA or NEPA Requirements.

According to Title 14 *California Code of Regulations*, Chapter 3, Guidelines for Implementation of CEQA:

“An EIR shall describe a range of reasonable alternatives to the project, or to the location of the project, which would feasibly attain most of the basic objectives of the project but would avoid or substantially lessen any of the significant effects of the project.”
(15 *California Code of Regulations* § 15126.6(a).)

Significant noise impacts are predicted for Lennox School District schools under each alternative considered, including the “No Action/ No Project” alternative. No alternative has been considered that would avoid or substantially lessen the noise impact upon Lennox schools as required by CEQA.

According to the Council for Environmental Quality, a NEPA analysis:

“ . . . shall inform decision makers and the public of the reasonable alternatives which would avoid or minimize adverse impacts or enhance the quality of the human environment. . . [including]. . . reasonable alternatives not within the jurisdiction of the lead agency.”

In this context, a proper NEPA analysis should include at least one alternative whereby a significant noise impact was avoided in Lennox schools by diverting the proposed increased heavy jet traffic to other airports.

6. The Analysis of Temporary Aircraft Noise Impacts Is Inadequate.

The main body of the SEIS/EIR does not appear to provide any analysis of temporary aircraft noise impact on Lennox School District schools, a discussion of how long they might last, or a recommendation for any mitigation measures. As with all significant adverse impacts, these construction impacts must be described and analyzed and mitigation measures presented.

7. Inadequate/Mislabeled Data in Supplemental Aircraft Noise Technical Report.

The *Supplemental Aircraft Noise Technical Report*, which presents the specific noise calculation results relevant to Lennox School District schools, provides data labeled as ‘DNL’ in Table S14. It is unclear whether this data is actually CNEL data that has been mislabeled. Since the project thresholds of significance are set in terms of CNEL rather than DNL, providing DNL data prevents the reader from looking at predicted CNEL impacts on specific Lennox School District schools.

8. Specific Noise Mitigation Measures for Lennox School District Facilities Are Not Identified in the SEIS/EIR.

According to Title 14 *California Code of Regulations*, Chapter 3, Guidelines for Implementation of CEQA:

“An EIR shall describe feasible measures which could minimize significant adverse impacts...the discussion of mitigation measures shall distinguish between the measures which are proposed by project proponents to be included in the project and other measures proposed by the lead, responsible or trustee agency or other persons which are not included but the lead agency determines could reasonably be expected to reduce adverse impacts if required as conditions of approving the project. This discussion shall identify mitigation measures for each significant environmental effect identified in the EIR.” (14 *California Code of Regulations* § 15126.4.)

Mitigation measure MM-LU-4, which incorporates noise mitigation measures for schools, is "subject to modification" based upon the results of further study. Details of the proposed 'further study' are not, however, provided for review. The proposed noise mitigation measures (further study excluded, because study alone will not do anything to mitigate the predicted noise impact) are not therefore clearly stated in the report.

9. The SEIS/EIR's Analysis of the Health Effects of Noise on Students is Flawed.

a. The SEIS/EIR improperly relies on a flawed FICON document.

The SEIS/EIR relies heavily on noise level standards from a document prepared by the Federal Interagency Committee on Noise ("FICON") entitled "Federal Agency Review of Selected Airport Noise Analysis Issues." This document is misrepresented in the report and should not be relied upon. The misrepresentation is to describe this document as a "study detailing the degree of speech understanding at various noise levels..." (SEIS/EIR, *Noise*, Section 4.1.2.1.2, p. 4-12.)

First, FICON is an interagency task force consisting of representatives from various government agencies. It does not consist of experts on noise or noise impacts on children who have appropriate scientific training and experience to critically evaluate and summarize a scientific body of literature.

Second, there are many individuals on FICON with clear conflicts of interest in assessing the scientific literature. The majority of FICON representatives work for federal agencies that are major producers of noise (e.g., Federal Aviation Administration ("FAA"), the U. S. military, National Aeronautics and Space Administration ("NASA").

Third, the entire FICON document devotes five pages to the topic of speech communication. No scientific analysis could "detail the degree of speech understanding" in such a limited manner. The uncritical acceptance of the FICON document reflects a serious lack of understanding and knowledge of the scientific literature on the effects of noise on children's learning and speech perception.

Fourth, some important data the FICON document relies upon are outdated and in some cases inaccurate. For example, Table 3.3 in the FICON document which is reprinted from a 30 year old Environmental Protection Agency ("EPA") document ("EPA Report") is widely rejected in the scientific community in its applicability to children's learning. Data from adults listening to a trained speaker conversing in the outdoors were used to develop this Table. It has long been known that children need a larger signal to noise ratio to comprehend speech than an adult, and noise effects in interior environments must take into account sound intensity and reverberation time (time for sound to decay). (American National Standards Institute, "Acoustical performance criteria design requirements and guidelines for schools.," ANSI S12.60-2002; World Health Organization, *Environmental Health Information, Guidelines for Community Noise*, 2000, Exhibit 20; Nelson, P. & Soli, S., "Acoustical barriers to learning: Children at risk in every classroom." *Language, Speech, and Hearing Services*. 31: 356-361, 2000; Picard, M., & Bradley, J.S., "Revisiting speech interference in classrooms." *Audiology*,

40: 221-244, 2001) The FICON document and the SEIS/EIR which relies primarily on the FICON document is replete with errors of this sort.

Fifth, the FICON document omits abundant research on airport noise and deficits in reading acquisition. More than 20 studies around the world (Evans, G.W. & Lepore, S.J., "Nonauditory effects of noise on children." *Children's Environments*, 10: 31-51, 1993; Kryter, K.D., "The handbook of hearing and the effects of noise." San Diego, Academic Press, 1994, Exhibit 21; World Health Organization, *Environmental Health Information, Guidelines for Community Noise*, 2001) including a dose response relationship (Green, K., Pasternack, B. & Shore, R., "Effects of aircraft noise on reading ability of school age children." *Archives of Environmental Health*, 37: 24-31, 1982, Exhibit 22) interventions to reduce noise (Bronzaft, A., "The effect of a noise abatement program on reading ability." *Journal of Environmental Psychology*, 1: 215-222, 1981) and most convincingly, a prospective, longitudinal study (i.e. the same children are compared before and after the opening of a major new airport) (Hygge, S., Evans, G.W., & Bullinger, M., "A prospective study of some effects of aircraft noise on cognitive performance in school children." *Psychological Science*, 13: 469-474, 2002, Exhibit 23), show significant deficits in reading from transportation related noise exposure.

b. The SEIS/EIR ignores the scientifically confirmed and well-established link between noise exposure and children's learning.

The SEIS/EIR relies heavily on FICON's flawed logic in developing its basic arguments. The SEIS/EIR states that "there is no reliable statistical relationship between the amount of aircraft noise exposure present and the degree of learning difficulty experienced by children at affected schools. . ." (SEIS/EIR, *Noise*, Section 4.1.2.1.2, p. 4-11.) First unless the SEIS/EIR consulting team includes individuals trained in statistics and research design methodology, this claim is suspect prima facie. Second, because there is very little data (consisting of one airport study (Green, K., Pasternack, B. & Shore, R. "Effects of aircraft noise on reading ability of school age children." *supra*) and one road traffic study (Lukas, J.S., DuPree, R.B. and Swing, J.W. *Effects Of Noise On Academic Achievement And Classroom Behavior*, *supra*.) to be exact, not zero as stated by FICON and uncritically repeated in the SEIS/EIR) showing a dose-response relationship between noise levels and learning deficits, the report presumes therefore there is no evidence to support a link between noise exposure and learning difficulties. This is patently false.

There are multiple sources of evidence to demonstrate a relationship between airport noise exposure and significant deficits in children's learning. Many studies show that aircraft noise is significantly related to deficits in reading acquisition (see reviews in Evans, G.W. & Lepore, S.J., "Nonauditory effects of noise on children." *Children's Environments*, 10: 31-51, 1993, Exhibit 24; Kryter, K.D. "The handbook of hearing and the effects of noise." *supra*; World Health Organization, *Guidelines*, 2001, *supra*.) Not one of these studies is cited in the FICON document or the SEIS/EIR. This is a glaring omission in an SEIS/EIR that is mandated by state and federal law to consider potential health and welfare costs and benefits of a proposed project. The focus on speech and communication should be at least matched by an analysis of the noise and reading acquisition literature.

In contrast to the FICON document, the SEIS/EIR briefly notes a more recent American National Standards Institute ("ANSI") classroom standard criterion established in "Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools," *supra*. (hereinafter referred to as "ANSI Report"). This document recommends lower levels of acceptable noise intensity in classrooms than FICON. The SEIS/EIR omits discussion of the World Health Organization ("WHO") noise criterion document, "Adverse Health Effects of Noise," Section 3, April 2001, (hereinafter referred to as the "WHO Report"), which predates the ANSI study by a few years. The WHO and ANSI standards converge on 35 dBA for an interior noise standard for elementary school classrooms. What is particularly important to understand is that unlike the FICON document, the ANSI and WHO reports were developed by scientists knowledgeable about noise and its human impacts. These reports are much more detailed and provide a thorough discussion and analysis of the evidence. In the case of the WHO Report, it represents a consensus statement of leading noise researchers in the world on the current level of knowledge about noise and its impacts and provides recommendations of acceptable noise standards to protect the public. Unlike the FICON document, the WHO and ANSI reports were also widely distributed to scientists in draft form for critical feedback, and then went through multiple iterations of revisions. There was substantially scientific peer review of the WHO and ANSI reports. This did not occur for the FICON document.

c. The SEIS/EIR entirely neglects the substantiated link between noise and other adverse learning and health effects on children.

The SEIS/EIR also does not consider evidence of other adverse learning and health effects on children chronically exposed to aircraft noise. These are widely available in the scientific literature. Children chronically exposed to noise suffer from motivational deficits. They persist less in achievement related contexts. Both laboratory (Glass, D.C. "Behavior patterns, stress, and coronary heart disease." Hillsdale, NJ: Erlbaum, 1977) and field studies of noise (Bullinger, M., Hygge, S., Evans, G.W., Meis, M. and von Mackensen, S., "The Psychological Cost of Aircraft Noise for Children," *supra*; Evans, G.W., Hygge, S. & Bullinger, M., "Chronic noise and psychological stress." *Psychological Science*, 6: 333-338, 1995, Exhibit 25) show that children are less likely to continue efforts in problem solving if they have been exposed to uncontrollable noise. These motivational deficiencies are believed to be caused by the uncontrollable nature of ambient noise exposure.

Constant exposure to a noxious, uncontrollable stressor like noise produces learned helplessness (Peterson, C., Maier, S. & Seligman, M.E.P., "Learned helplessness." NY: Oxford University Press, 1993). Individuals learn that regardless of their efforts to cope with an adverse environmental condition, they cannot do anything about it. The outcomes of their behaviors are noncontingent on their behaviors. It is worth noting that the most common way learned helplessness is produced in human laboratory studies, is to expose individuals to uncontrollable noise. There is very strong evidence from human experiments that exposure to uncontrollable noise can produce significant decrements in task persistence. Field studies with children indicate parallel trends from chronic exposure to aircraft noise (See for reviews Cohen, S., "Aftereffects of stress on human performance and social behavior: A review of research and theory." *Psychological Bulletin*, 88: 82-108, 1980, Exhibit 26; Evans, G.W., "Environmental stress and health." In A. Baum, T. Revenson & J.E. Singer (Eds.), *Handbook of Health Psychology*. Mahwah, NJ: Erlbaum, 2001, Exhibit 27; Glass, D.C., & Singer, J.E., "Urban stress: experiments

on noise and social stressors.” NY: Academic Press, 1972; Peterson, C., Maier, S. & Seligman, M.E.P. “Learned helplessness.”, *supra.*) The effect of learned helplessness is compounded for Lennox School District students because learning does not only occur in the classroom. These children also learn at home (i.e. reading and homework) with chronic exposure to aircraft noise.

Additionally, there are several studies documenting links between chronic noise exposure in children and elevated blood pressure. There are no dose response data, but several studies with different research designs (cross-sectional, intervention, longitudinal) show that airport noise exposure is associated with higher blood pressure in children. (See for reviews Evans, G.W. “Environmental stress and health.” *supra.*; Ising, H. Babisch, W., & Kruppa, B., “Acute and chronic noise stress as cardiovascular risk factors.” *Noise and Health*, 4: 37-48, 1999; World Health Organization, *Environmental Health Information, Guidelines for Community Noise*, 2001, *supra.*) A smaller number of studies also find evidence of elevated stress hormones from exposure to airport noise (Evans, G.W., Bullinger, M. and Hygge, S., “Chronic Noise Exposure and Physiological Response: A Prospective Study of Children Living Under Environmental Stress.” *Psychological Science*, Vol.9, No.1, January 1998, Exhibit 28; Ising, H., et al. “Acute and chronic noise stress as cardiovascular risk factors.”, *supra.*) It is well known that children with higher blood pressure will tend to have higher blood pressure as adults.

10. The SEIS/EIR’s Proposed Noise Study is Inadequate.

a. LAWA may not postpone its proposed noise study absent a commitment by LAWA to mitigate.

The California Environmental Quality Act requires that, whenever feasible, all impacts must be mitigated for any project that is carried out by or approved by a public agency. California *Public Resources Code* §§ 21002, 21002.1(b). Thus, significant effects on the environment must be either eliminated or *substantially* minimized where feasible. (*Berkeley Keep Jets Over the Bay Committee v. Board of Port Commissioners* (2001) 91 Cal.App.4th 1344, 1355.)

According to the SEIS/EIR, LAWA will initiate a study of the relationship between aircraft noise levels and the ability of children to learn. (SEIS/EIR, *Land Use*, Section 4.2, p. 4-210.) Based upon this study, LAWA will set a new threshold of significance for classroom disruption. (*Id.*)

Nonetheless, the SEIS/EIR is vague, inconclusive and inconsistent with respect to actual mitigation. The SEIS/EIR makes no clear statement or commitment to mitigate the impacts even after establishing the new threshold of significance discussed above.

According to California law, LAWA must make a binding “commitment” to achieve a desired level of mitigation. (*Sacramento Old City Association v. City Council of Sacramento* (1991) 229 Cal.App.3d 1011, 1028.) One manner in doing so is to effectuate “specific performance criteria articulated at the time of project approval.” (*Id.* at 1029.) Without either a binding commitment or a performance standard, the CEQA analysis is flawed.

For example, the SEIS/EIR states that “any schools found to exceed a newly established threshold of significance for classroom disruption shall be incorporated into the ANMP administered by LAWA.” (SEIS/EIR, *Land Use*, Section 4.2, p. 4-210.) According to the SEIS/EIR, the ANMP performance standard is as high as 45 CNEL. (SEIS/EIR, *Land Use*, Section 4.2, p. 4-198.) Since the new threshold of significance will in all likelihood be lower than 45 CNEL, reliance on the ANMP performance standard would render the new threshold immaterial for mitigation purposes.

Also, conflicting language in the SEIS/EIR creates ambiguity as to whether LAWA will provide substantial mitigation. The SEIS/EIR states that mitigation measures would “mitigate schools that are impacted by significant single event levels through further study of the relationship between the learning and aircraft noise exposure levels, and the subsequent sound insulation of schools where impacts are shown to be significant.” (SEIS/EIR, *Noise*, Section 4.1, p. 4-80.) The *Supplemental Aircraft Noise Technical Report*, however, hedges by associating eligibility for mitigation with the CNEL levels in the Settlement Agreement. (Section 6.2.3, p. 154.) Additionally, it states that “the potential for additions to the sound insulation program for schools will be revisited as part of LAWA’s continuing environmental management responsibilities.” (*Id.*)

The SEIS/EIR does not state whether LAWA will mitigate to levels below significance (i.e. below the new threshold of significance). Nor does the SEIS/EIR provide a “standard of performance” for noise mitigation. It also does not clarify whether this mitigation will occur in schools it believes are otherwise “compatible” under Title 21. (See, e.g., SEIS/EIR, *Environmental Justice*, Section 4.4.3.5.1.2, p. 4-329.)

Although the SEIS/EIR acknowledges the impact of aircraft noise on children’s learning, it does not commit to mitigation. The SEIS/EIR’s inconclusive approach circumvents the mitigation analysis called for by CEQA.

b. A deferred noise analysis is inappropriate.

Possible impacts must be studied as early as possible to avoid deferment of formulation of mitigation measures. (See, *Sundstrom v. County of Mendocino* (1988) 202 Cal. App. 3d 296, 307.) In general, “an environmental assessment, including a statement of the mitigation measures, may not be deferred until a future study or project.” (*Rio Vista Farm Bureau Center v. County of Solano* (1992) 5 Cal.App.4th 351.)

There is substantial evidence currently before LAWA that significant impacts of aircraft noise on children’s learning will occur. Despite this, LAWA is deferring the assessment of this impact. CEQA requires environmental review at the earliest feasible stage in the planning process. California *Public Resources Code* Section 21003.1; *Sundstrom v. County of Mendocino*, 202 Cal. App. 3d 296, 307.

In this case, there is no justifiable reason for delaying the study or not initiating the study at an earlier date. In September of 2001, in response to the Original EIS/EIR, the Lennox School District analyzed an abundance of studies and academic research regarding the relationship between aircraft noise and children’s learning, ‘learned helplessness’ and high blood pressure.

LAWA does not present a satisfactory reason for its failure to conduct or initiate its proposed study at that time, nearly two years prior to release of the Supplement, or any time since then. Thus, the SEIS/EIR fails in its obligation to conduct the study at the earliest feasible stage in the process.

Also, as a result, the SEIS/EIR fails to meet the requirement of “completeness and a good faith effort at full disclosure.” (*Berkeley Keep Jets Over the Bay Committee v. Board of Port Commissioners* (2001) 91 Cal.App.4th 1344, 1355.)

c. Failure to conduct a study prior to publishing the SEIS/EIR is against public policy.

The oversight in failing to conduct a noise study in and of itself may seem inconsequential, however, in face of overarching public policy considerations, it is significant. Public policy dictates that, “in the absence of overriding circumstances, the CEQA process demands that mitigation measures be timely set forth, that environmental information be complete and relevant, and that environmental decisions be made in an accountable arena.” (*Gentry v. City of Murrieta* (1995) 36 Cal.App.4th 1359, 1393-1394.) Otherwise, the process diminishes the influence of decisionmaking in CEQA by not allowing the public to review the environmental impacts and provide comments to the lead agency. “Public and agency review” has been called the “strongest assurance of the adequacy of the EIR. [Citations]” (*Sundstrom v. County of Mendocino* (1988) 202 Cal. App. 3d 296, 308.) Absent this public review, LAWA is not accountable to mitigation measures for a significant impact caused by aircraft noise on children’s learning.

Moreover, CEQA’s very purpose “is to inform the public and its responsible officials of the environmental consequences of their decisions before they are made. Thus, the EIR ‘protects not only the environment but also informed self-government.’[Citations.]” (*Berkeley Keep Jets Over the Bay Committee v. Board of Port Commissioners* (2001) 91 Cal.App.4th 1344, 1354.) The lack of early disclosure and public review completely disregards and undermines the CEQA process.

d. The proposed noise study must meet stringent scientific standards to be valid.

LAWA proposes to commission a study to determine a dose-response relationship between aircraft noise exposure and learning deficits in children. (SEIS/EIR, *Land Use*, Section 4.2, p. 4-210.) This is a worthy scientific endeavor that will entail a large, complex, and lengthy process that will cost an enormous sum of money. The proposed study will require considerable expertise, experience, and knowledge in formulating, conducting, analyzing and interpreting complex data. As currently described in the SEIS/EIR, it is impossible to evaluate the potential merits of the proposed study because major elements of the most basic scientific information are not presented about the study.

No scientific research proposal can be evaluated for its potential merit without a careful, even handed and critical review of the existing literature bearing on the topic. The current document provides an incomplete, outdated, and highly biased overview of the literature. It

relies too heavily on one summary review (FICON). Furthermore no conceptual arguments are developed linking the literature overview with the proposed study. In scientific research, investigators must build a conceptual and methodological rationale for any proposed study. The current document does not do this.

The SEIS/EIR needs to include a statistical power analysis to estimate the number of participants to be included in the proposed study. Standard scientific review criteria for empirical research proposals call for statistical estimates of effect sizes from existing literature and their incorporation into research proposals. This power analysis would need to address the overall sample size for establishing a dose response function between noise and each learning outcome of interest. Furthermore, critical subsample power estimates would need to be incorporated such as ESL and non-ESL children, children suffering permanent and temporary hearing loss (a very common occurrence among elementary school children because of ear infections) and grade levels given likely age differences in susceptibility to adverse noise impacts on reading acquisition as well as speech perception. For example, according to ANSI:

“Limitations in vocabulary and in the ability to ‘fill in the blanks’ when partial communication occurs in difficult listening situations have been shown to reduce intelligibility for children with limited English Proficiency, again despite normal intelligibility in quiet environments. These children may require 2 to 5 dB more favorable signal-to-noise ratios in difficult listening situations to achieve the same level of intelligibility as children with normal English proficiency. (Citations omitted.) (ANSI, “Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools.”, *supra*.)

This is of particular significance to Lennox School District due to its having a student body consisting of 71.2% “English Learner” students. (See Part One, Section 2a., *supra*.) In addition, ANSI estimates that hearing impairments caused by ear infections are,

“estimated incidence as high as 25% to 30% among kindergarten and first grade children. . . . Signal to noise ratio improvements of 3 dB to 5 dB together with increases in absolute speech sound levels of 10 dB to 30 dB are necessary for children with these impairments to achieve the same level of speech intelligibility in classrooms with high background noise.” (ANSI, “Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools.”, *supra*.)

The research design of the proposed study would also need to address in detail how duration of exposure (e.g., months in residence) and home noise exposure would be incorporated into a study of schools varying in aircraft noise exposure.

Given a thorough statistical power analysis is needed to ensure that the appropriate number of participants are included overall and in critical subgroups in order to provide the necessary sensitivity to detect potential adverse effects, a thorough sampling plan also needs to

be developed. The following issues must be addressed in the SEIS/EIR with respect to the proposed study: How and where will participants be sampled and what special sampling techniques will be used to ensure adequate representation of critical subgroups (e.g., ESL)? Will children with temporary or permanent hearing loss be included in the study and how will these classifications be determined? Will data be collected in one or multiple school districts and if the latter, how will differences in reading curricula be handled? Will data be collected only once, yielding a cross-sectional study or will a panel design be developed to monitor children's learning trajectories over time? If the latter research design is incorporated, at what ages would children be monitored and how often would data be collected? If a longitudinal design is incorporated, how will attrition be dealt with both in the research design and in data analysis?

No information is provided in the SEIS/EIR about the manner in which the proposed study would be conducted and what measures of learning would be incorporated. Is the primary focus on chronic or acute noise? This has dramatic implications for interpretation of the data and bears significantly on procedural conduct of the study itself. For example, reliance on archival records of standardized tests confounds chronic and acute noise exposure since the tests are taken during airport operational periods.

Outcome measures (e.g., reading acquisition, speech perception) need to be described, including at a minimum their basic psychometric properties (e.g., reliability, validity) and their appropriateness for use in a culturally diverse, multi-language sample.

How exactly will noise exposure be estimated and what metrics will be used? The SEIS/EIR glosses over critical distinctions in noise metrics such as L_{MAX} , L_{LEQ} , CNEL, and time above peaks. The authors of the proposed study need to say what metric(s) they would use and provide a rationale, discussing in depth the strengths and weaknesses of each alternative. How will reverberation time be monitored and incorporated into data analyses and interpretation? In interior settings, reverberation time influences speech intelligibility. The very difficult issue of exposure estimation also requires discussion. Where and when will noise exposure be measured? Children learn in the classroom, on the playground, and at home. A narrow focus on school noise level changes ignores the potential influence of changes in home noise levels caused by expanded airport operation.

There is no data analytic plan included in the study proposal detailing precisely how the results would be analyzed. Such a plan at a minimum would describe what statistical techniques would be used and how controls for factors with known covariation with noise and learning would be dealt with in the analyses. For example, how will the proposed study statistically or methodologically handle the co-mingling of income, ethnicity, noise exposure, and learning?

It is basic scientific practice to address the kinds of issues briefly summarized above in research proposals to obtain funding to conduct research. Scientific review panels for the National Science Foundation or the National Institutes of Health routinely consider and evaluate the scientific merits of proposals using such criteria. This is widely understood and supported by scientists. Major foundations that support scientific research subscribe to similar scientific review criteria as well. Written proposals that address the types of issues and questions raised above are typical, routine practice engaged in by scientists *prior to conducting research*.

Because the SEIS/EIR ties the proposed study to some critical policy decisions, it is critical to provide some additional material to the document under review. In particular, regulatory bodies and the public need to know more about how the results would be used to determine mitigation measures. For example, what indices of deficit would be considered significant and trigger mitigation? If reading acquisition is delayed on average by six months and for even longer for ESL children, would LAWA consider this sufficient to incorporate mitigation? What percentage of loss in speech perception is considered sufficient to warrant mitigation? Parallel questions need to be discussed for all health and welfare outcomes judged pertinent to the study design.

There is precedent in California and federal environmental regulatory procedures to incorporate a margin of safety in standards to protect vulnerable subgroups of the population. For example air pollution standards both in California and at the federal-level mandate protection for asthmatic children. (See Cal/EPA, *Staff Report: Public Hearing to Consider Amendments to the Ambient Air Quality Standards for Particulate Matter and Sulfates*. Air Resources Board and Office of Environmental Health Hazard Assessment, May 2002, <http://www.arb.ca.gov/research/aags/std-rs/pm-final/pm-final.htm>; see also, USEPA, *Review of the National Ambient Air Quality Standards for Particulate Matter: Policy Assessment of Scientific and Technical Information*. Office of Air Quality Planning and Standards, June 2001, <http://www.epa.gov/ttn/oarpg/t1/reports/pmstdrft.pdf>.) How will determinations be made of which groups of children are vulnerable and in need of additional protection from elevated noise levels at school and in their homes? What margin of safety will be incorporated to protect these vulnerable subgroups, once determined?

Decisions about criteria for mitigation and protection of vulnerable subgroups in the population are both scientific and political. Since one of the major reasons for the proposed study in the SEIS/EIR is to determine mitigation procedures, government bodies with regulatory responsibility, as well as the public, must have the opportunity for discussion and review of the criteria that will be used to determine such critical policy decisions. The present document is silent on these issues therefore precluding regulatory and public scrutiny as mandated in CEQA and NEPA.

PART FOUR

THE EMISSIONS, MODELING, MITIGATION MEASURES AND HEALTH IMPACT ANALYSIS OF THE SEIS/EIR IS INADEQUATE

CEQA requires the EIS/EIR to “identify and focus on” significant environmental effects of proposed projects. (14 *California Code of Regulations* § 15126.2.) “Direct and indirect significant effects of the project on the environment shall be clearly identified and described, giving due consideration to both the short-term and long-term effects.” (*Id.*) The EIS/EIR also must describe “feasible measures which could minimize significant adverse impacts.” (14 *California Code of Regulations* § 15126.4.) The EIS/EIR fails to adequately do so.

1. The Emissions Estimations in the SEIS/EIR Violate CEQA.

The emissions estimates in the SEIS/EIR for jet aircraft and storage and handling of fuels may be underestimated. Correction of this underestimation will result in increased pollutant concentrations that may result in exceedances of the National Ambient Air Quality Standards (NAAQS) and California Ambient Air Quality Standards (CAAQS) as well as increases in off-site cancer risks and noncancer hazard indices for off-site populations.

a. Jet Aircraft Emission Estimates May Be Underestimated As the Methodology Used to Estimate Particulate Emissions from Jet Aircraft Is Unclear and May Be Flawed.

To estimate particulate matter less than 10 microns (PM_{10}) emission rates from aircraft for the EIS/EIR, Los Angeles World Airports (LAWA) used information from three sources: (1) fourth edition of AP-42; (2) Whitefield and Hagen Study; and (3) the 1994 California FIP Docket. (Original EIS/EIR, *Technical Report 4*, Attachment H.) The emission rate data from these studies are combined; the combined data are plotted for each of the four aircraft operating modes. Based on these plots, a relationship between fuel usage and PM_{10} emission rate is interpolated.

A review of the data shows the first and second studies to be in approximate agreement; the FIP Docket provides an alternate data set. As there is approximately an order of magnitude more FIP Docket data, the data from this study dominate the results. If the FIP Docket data were removed from the combined data set, it is clear that the relationship between fuel usage and the PM_{10} emission rates would change and the estimated total PM_{10} emissions from aircraft would also change.

Based on the information presented in the EIS/EIR, it is unclear how the FIP Docket data are used in the PM_{10} emission rate analysis. It appears that a relationship between PM_{10} emissions and fuel usage is derived from a graphical representation of a relationship between particulate mass concentration and smoke number (i.e., from a plot of an equation relating PM concentration and smoke number).

There are two issues with this derivation. First, it is not clear how a relationship between fuel usage and PM_{10} emissions is derived from a plot of particulate mass concentration versus smoke number. Second, because the particulate mass concentration versus smoke number data appear to be simply a plot of some unknown equation, the number of data points taken from this graph seems to be arbitrary. Since the number of points taken from this graph is approximately 10 times greater than the number of data points available from the other two studies, it appears that LAWA may have arbitrarily weighted the combined data set heavily towards the FIP Docket data and away from the AP-42 and Whitefield and Hagen data.

Aircraft emissions of PM_{10} are potentially underestimated. An increase in PM_{10} emissions will result in an increase in off-site concentrations of PM_{10} . As noted below, the potential noncancer health impacts associated with these PM_{10} emissions have not been

quantified in the EIS/EIR. Inclusion of additional PM₁₀ emissions may result in exceedance of the noncancer hazard index for off-site populations.

At a minimum, LAWA needs to clarify the approach used to develop the FIP Docket data; conduct a sensitivity analysis to determine the importance of the FIP Docket data to their results; and, if necessary, remove arbitrary weighing of FIP Docket data over other data sets, correct the PM₁₀ emission rates, and remodel off-site PM₁₀ concentrations.

- b. Potentially significant evaporative emissions of toxic air contaminants resulting from the storage and handling of organic liquids may not have been quantified.**

LAWA does not include volatile organic compound (VOC) emissions from organic liquid storage and transfer in their Industrial Source Complex Short Term 3 (ISCST3) modeling of toxic air pollutant emissions. They assume that: (1) storage emissions are almost exclusively from Jet A fuel; (2) emissions of Jet A vapor do not contain significant quantities of the toxic air pollutants modeled; and (3) limited future operations of gasoline fueling would include vapor recovery and therefore result in minimal emissions of air toxics.

There are three problems with this exclusion of VOC emissions. First, diesel fuel and gasoline are used at the airport. LAWA should provide data to show that storage and resulting emissions of these fuels are insignificant. Second, LAWA should provide justification for the assumption of no toxic air pollutants in Jet A vapor. Third, LAWA should provide some screening calculations to validate their assumption that gasoline fueling would result in insignificant emissions of air toxics (especially benzene).

Toxic air emissions from storage and handling of organic liquids may have been underestimated. An increase in toxic air emissions will result in increases in off-site cancer risks and noncancer hazard indices for off-site populations.

At a minimum LAWA needs to quantitatively demonstrate that emissions of toxics from storage and handling of diesel fuel and gasoline are insignificant; and provide a speciated chemical list for Jet A fuel.

2. The Modeling Approach of the EIS/EIR Violates CEQA.

The modeling approach presented in the EIS/EIR has several significant flaws that result in underestimation of both criteria and toxic pollutants impacts on nearby receptors. The analysis of the emission impacts is inadequate, the methodology used to estimate plume rise is flawed, the assumption of no downwash is not justified, the meteorological data used in the modeling is inadequate, the conversion of sulfur dioxide to sulfate is not addressed, and finally, secondary formation of toxic pollutants and deposition effects are ignored. These flaws result in an underestimate of ambient pollutant concentrations. Correcting these flaws will result in an increase in pollutant concentrations and may result in exceedances of the NAAQS and CAAQS as well as increases in off-site cancer risks and noncancer hazard indices for off-site populations.

- a. **The extent to which emissions from motor vehicles traveling the I-405 and I-105 interstate highways have been included in the air quality analysis is unclear. Emissions of carbon monoxide, toxic air contaminants, particulate matter, and ozone precursors from these sources may be underestimated. Airborne concentrations of these chemicals at locations downwind from the freeways (e.g., community of Lennox) may be underestimated accordingly.**

The I-405 and I-105 interstate highways are major sources of air pollution in the immediate project area. Motor vehicle emissions from these roadways negatively impact air quality on local and regional scales. These roadways produce elevated concentrations of directly-emitted chemicals (including carbon monoxide, benzene, 1,3-butadiene, formaldehyde, and diesel exhaust) at locations immediately downwind from the roadways, and contribute to elevated ozone and secondary particulate matter (i.e., particulate matter formed in the atmosphere - a major source of visibility impairment) concentrations over a broader area. However, it appears that the EIS/EIR analysis neglects to include emissions from motor vehicles traveling on the I-405 and I-105 roadways, except for carbon monoxide emissions from short segments (only) of these roadways which are considered in the analysis of carbon monoxide impacts near traffic intersections.

Exclusion of motor vehicle emissions from the I-405 and I-105 interstate highways would result in underestimation of airborne concentrations of carbon monoxide, benzene, 1,3-butadiene, formaldehyde, diesel exhaust, and other toxic air contaminants at locations downwind from the roadways, e.g., within the community of Lennox. Estimated concentrations of carbon monoxide near roadway intersections and areas downwind of the I-405 and I-105 roadways (e.g., intersections 46 and 107 on Figure 4.3.2-1 from the Original EIS/EIR) would be greater if all carbon monoxide emissions from motor vehicles on the freeways were considered, and may comprise significant air quality impacts at these locations. Estimated cancer and noncancer health risks for schoolchildren and residents located downwind from I-405 and I-105 (e.g., as predicted for Alternative D in Section 4.24 of the SEIS/EIR) would be greater if all pollutant emissions from motor vehicles were considered, and may comprise significant impacts for these people.

LAWA should clarify the extent to which emissions from motor vehicles traveling the I-405 and I-105 interstate highways are or are not included in the air quality and health risk analyses. If pollutant emissions from these major sources are not considered, the emissions, air quality modeling, and human health risk analyses should be revised to incorporate these potentially significant sources of pollution or justification should be provided to support their omission from the analysis.

- b. The extent to which "sound walls" and other structures have been considered in the dispersion modeling of carbon monoxide and toxic air contaminants is unclear. Airborne concentrations of carbon monoxide and toxic air contaminants at locations where "downwash" and "cavity" effects occur may be underestimated.

Obstacles to air flow such as walls and buildings create localized flow phenomena known as "downwash," "cavity effects," and "eddies," typically on the downwind side of the obstacle, which results in buildup of pollutant concentrations. For example, pollutant concentrations between tall urban buildings may be 2 to 20 times higher than in the surrounding area (United States Department of Energy, 1984). A sound wall built parallel to and downwind from an interstate highway would result in elevated pollutant concentrations both within the roadway and also along the leeward side of the wall (away from the roadway) due to downwash; this effect is illustrated in the figure below. (United States Department of Energy (1984) *Atmospheric Science and Power Production*, Darryl Randerson, Editor, Technical Information Center, Office of Scientific and Technical Information, DOE/TIC-27601 (DE84005177).)

(b) Wind incident at an angle on a long obstruction creates a spiraling zone in the near wake; the speed ratio Ψ has a maximum value of about 1.4.

It is not clear to what extent that increased pollutant concentrations caused by building- and structure-induced flow effects have been considered in the EIS/EIR analysis. It is noted that building downwash and cavity effects are assumed to be negligible with respect to aircraft emissions because the emissions sources (aircraft) are located within the airport and away from any receptor locations which may be influenced by building effects. (Original EIS/EIR, Technical Report 4, Attachment A, p24.) However, it is unknown if downwash/cavity effects are considered in the dispersion modeling of carbon monoxide and toxic air contaminants, especially those emitted from motor vehicles.

The Original EIS/EIR states that "site geometry and characteristics" are considered in the dispersion modeling of carbon monoxide from roadway intersections. (Original EIS/EIR, Appendix G, p. 28.) It is not stated which, if any, particular roadway geometry features are

incorporated into the analysis of any particular intersections. For example, it is unknown whether sound walls or other structures are included in the analysis of roadway intersections near the I-405 interstate highway. The presence of a sound wall or similar structure east of I-405 would cause elevated concentrations of carbon monoxide and other toxic air contaminants emitted by motor vehicles along the leeward side of the structure. We conclude that airborne concentrations of carbon monoxide and toxic air pollutants may be underestimated at locations where walls and buildings produce downwash effects, including the area downwind (east) from I-405.

c. The methodology used to estimate plume rise from jet aircraft is questionable and requires further justification.

LAWA determines the plume rise of hot exhaust gas from jet aircraft engines based on a heat balance to determine the heat flux and the equivalent exit velocity that would result. (Original EIS/EIR, *Technical Report 4*, p. 19.) To calculate this exit velocity, they make four critical assumptions. First, the jet engine exhaust gas temperature is fixed and unrelated to the heat flux. Second, as the exhaust gas from the jet engine begins to slow (in the horizontal plane) and begins to move vertically upward as a plume, the diameter of the plume (in the vertical plane) may be estimated by the wingspan of the jet.

Third, the temperature of the plume is equal to the jet engine exhaust gas temperature. As there are no ambient heat sources, this implies that the movement of the exhaust gas is adiabatic, isothermal, and there is no rapid expansion of exhaust gas. Finally, the temperature of ambient air is assumed to be 293 Kelvin (K). Calculated exit velocity, plume temperature, and plume diameter were then input into ISCST3 to determine plume rise.

There are three problems with this approach. First, the temperature of the plume is assumed equal to the temperature of the exhaust gas. Given isothermal movement, this is only true if the total mass per second of air leaving the jet engines equals the mass per second of air moving up in the plume. LAWA should check their calculations to be sure that this is true, otherwise the plume rise calculations may be in error.

Second, the implied assumptions of isothermal movement and slow expansion of exhaust gas are physically unrealistic. It is likely that exhaust gas will expand rapidly when exiting the jet engine and cooler, ambient air will be entrained into exhaust gas as it moves away from the jet engine. Both of these effects will tend to lower the temperature in the plume. LAWA should perform a sensitivity analysis to determine the quantitative influence of these phenomena on the resulting plume rise.

Finally, the temperature of the ambient air should be consistent with the average temperature data used in the ISCST3 model runs. LAWA should average the temperatures in the meteorological data set used in the model runs to determine the correct average ambient temperature.

Plume rise may be overestimated. If so, concentrations of NO₂, PM₁₀, and air toxics resulting from aircraft emissions may be underestimated. Increases in concentrations of these

pollutants may result in exceedances of the NAAQS and CAAQS as well as increases in off-site cancer risks and noncancer hazard indices for receptor populations.

At a minimum LAWA needs to check their calculations to ensure conservation of mass; conduct a sensitivity study to determine the quantitative influence of rapid expansion of exhaust gas and entrainment of ambient air on plume temperature; and calculate the plume rise with the correct average ambient temperature.

d. The assumption that building downwash is negligible requires further justification.

LAWA believes that building downwash will not be significant based on their assumption that the nearest receptor is too far off-site. (Original EIS/EIR, *Technical Report 4*, p 24.) LAWA should validate this assumption by modeling the most conservative source-receptor geometry, with building downwash included, to ensure this statement is correct. These results should be presented in *Technical Report 4*.

Off-site impact from airport emissions may be underestimated. If so, concentrations of criteria pollutants and air toxics resulting from airport emissions may be underestimated. Increases in concentrations of these pollutants may result in exceedances of the NAAQS and CAAQS as well as increases in off-site cancer risks and noncancer hazard indices for receptor populations.

LAWA needs to conduct a sensitivity study to show that building downwash effects are negligible.

e. The meteorological data set used may be inadequate relative to EPA and SCAQMD recommendations.

LAWA used the most recent meteorological data collected at LAX. These data consist of hourly surface and upper air data from the LAX meteorological observation station operated by the SCAQMD for the 12-month period beginning March 1, 1996 and ending February 28, 1997.

As recommended by EPA, "five years of representative meteorological data should be used when estimating concentrations with an air quality model. (USEPA, *Guideline on Air Quality Models (Revised)*, Original EIS/EIR Response Exhibit 14. Office of Air Quality Planning and Standards, Research Triangle Park, NC 27711, EPA-450/2-78-027, 1986, August 1995 update.) Consecutive years from the most recent, readily available 5-year period are preferred." SCAQMD recommends the use of the 1981 dataset. Accordingly, LAWA should conduct their air modeling with either the most recent five years of data from the LAX station, selecting the most conservative year results as representative of maximum long-term pollutant concentrations resulting from emissions associated with LAX or use the 1981 dataset. Furthermore, this five-year data set or 1981 dataset should be used to estimate average temperature (plume rise), mixing heights (EDMS), and wind speed (volume source height) used in other calculations and analyses.

Pollutant ambient air concentrations may be underestimated. If so, concentrations of criteria pollutants and air toxics resulting from emissions associated with expansion of LAX may be underestimated. Furthermore, the location of the maximum off-site impacts may also change. Increases in concentrations of these pollutants may result in exceedances of the NAAQS and CAAQS as well as increases in off-site cancer risks and noncancer hazard indices for receptor populations.

At a minimum LAWA needs to (1) conduct a sensitivity study to determine which year of LAX meteorological data is the most conservative or use the SCAQMD designated 1981 year of data; (2) if different from the meteorological data used in their analysis, redo all air modeling with the correct meteorological data; and (3) use the most conservative meteorological data set to estimate meteorological data used in other calculations and analyses.

f. Atmospheric conversion of sulfur dioxide to sulfate may be significant and is not addressed.

LAWA has ignored production of sulfate from sulfur dioxide (SO₂) due to the complexity of sulfate-formation mechanisms. LAWA assumes that all sulfur emitted by sources remains in the atmosphere as SO₂. This assumption is not conservative; the California Ambient Air Quality Standard (CAAQS) for sulfate is more than six times lower than the CAAQS for SO₂ (6.2 parts per billion by volume (ppbv) compared to 40 ppbv).

Formation chemistry for conversion of nitrogen oxides (NO_x) to nitrogen dioxide (NO₂) is equally complex, if not more so. The Tier 2 Ambient Ratio Method (ARM) recommended by USEPA in the Guideline on Air Quality Models for converting total NO_x to NO₂ values may be modified to estimate formation of sulfate from SO₂. (USEPA, *Guideline on Air Quality Models, supra.*) LAWA could gather the most recent years of data on the annual average SO₂-to-sulfate ratio near LAX and use this data to estimate the formation of sulfate.

The concentration of sulfate in ambient air is underestimated. Increases in concentrations of sulfate may result in an exceedance of the CAAQS for sulfate. As exposure to sulfate causes respiratory irritation, underestimating the ambient sulfate concentration may significantly underestimate the numbers and types of respiratory illnesses that may be observed in nearby populations, particularly young children who may be especially sensitive to respiratory irritants.

At a minimum LAWA needs to develop an approach to model sulfate chemistry and estimate sulfate concentrations.

g. Secondary formation of toxic air pollutants may be significant and is not addressed.

LAWA has ignored the production of several toxic air pollutants formed in the atmosphere due to reactions among other pollutants (i.e., formed by secondary reactions). As outlined in the EPA's guidance on Air Dispersion Modeling of Toxic Pollutants in Urban Areas, these pollutants should be included in any air toxic analysis. (USEPA, *Draft Air Dispersion Modeling of Toxic Pollutants in Urban Areas - Guidance, Methodology and Example*

Applications. Emissions, Monitoring and Analysis Division (MD-14), Office of Air Quality Planning and Standards, Research Triangle Park, NC 27711, EPA-454/R-99-021, July 1999, Original EIS/EIR Response Exhibit 13.) The pollutants formed by secondary reactions include formaldehyde, acetaldehyde and acrolein.

For example, formaldehyde may be formed in the atmosphere through photolysis or oxidation of other, directly-emitted hydrocarbon species:

An estimate of concentrations based on secondary reactions is needed and should be added to the ISCST3 output. LAWA should use EPA's OZIPR screening model to estimate the secondary formation of these pollutants. (USEPA, *Draft Air Dispersion Modeling, supra.*) Case studies provided in EPA's guidance document show secondary formaldehyde as the major component of total atmospheric formaldehyde (a ratio of 4 to 1 over primary formaldehyde).

If the total ambient formaldehyde concentration attributable to the project were increased by a factor of 5 to account for secondary formation, the contribution from formaldehyde to total absolute cancer and noncancer risks would increase by the roughly the same factor for all years/alternatives. The absolute contributions of formaldehyde to total cancer and noncancer risks in different years/alternatives are not presented in the SEIS/EIR (see comment 4[f]).

The concentrations of formaldehyde, acetaldehyde and acrolein in ambient air are underestimated. Increases in concentrations of these pollutants may result in increases in off-site cancer risks and noncancer hazard indices for receptor populations. At a minimum LAWA needs to model formaldehyde, acetaldehyde and acrolein chemistry.

h. The exclusion of deposition effects from the multipath risk analysis is not justified.

LAWA has neglected to include deposition effects and associated multipathway risk analysis based on conclusions presented in the deposition report, included as Attachment Y to Original EIS/EIR *Technical Report 4*. In this report, LAWA claims that a direct correlation between airport operations and deposition could not be determined.

Nonetheless, LAWA goes on to state, "The limited monitoring duration [less than two weeks] and time of year, while required to meet project schedule requirements, were not optimal for dry deposition monitoring. The *limited nature* [italics added] of this study did not allow for the determination of summertime maximum deposition rates or provide data necessary to perform a mass balance analysis . . ." (Original EIS/EIR, *Technical Report 4*, Attachment Y.)

LAWA is stating that the study was too short to make *any definitive conclusions* and further deposition sampling will be required before the deposition impact of airport emissions on off-site soils can be quantified. In other words, the study is incomplete.

If the study is limited and incomplete, there is no rational reason why LAWA should exclude deposition effects and the associated multipathway risk analysis. Furthermore, the deposition sampling locations selected for this study appear to be outside of the maximum particulate matter plume predicted by LAWA's ISCST3 modeling, further undercutting the already limited nature of this deposition study. Therefore, pending a more complete deposition study, LAWA should include deposition effects and a multipathway risk analysis in the EIS/EIR.

Deposition effects have been improperly excluded from consideration. Soil concentrations of pollutants sorbed to particulate matter have been underestimated. Increases in soil concentrations of these pollutants may result in increases in off-site cancer risks and noncancer hazard indices for receptor populations.

At a minimum LAWA needs to estimate concentrations of pollutants sorbed to particulate matter in soil based on emissions occurring over the duration of the project; and based on these soil concentrations, run a multipathway risk analysis to determine the health impacts of these soil concentrations.

3. The Mitigation Measures Proposed By The SEIS/EIR Violate CEQA.

a. The mitigation measures proposed in the SEIS/EIR have not met all requirements outlined in the SCAQMD CEQA Handbook.

The mitigation measures proposed in the SEIS/EIR have not met all requirements outlined in the SCAQMD CEQA Handbook. Before mitigation measures may be applied to total project emissions they must meet several criteria. The mitigation measures proposed in the SEIS/EIR have not demonstrated compliance with three of these criteria.

Several proposed mitigation measures do not meet the required criteria. Therefore, mitigated emission estimates may be too low. Increases in emissions of mitigated pollutants may result in exceedances of the NAAQS and CAAQS as well as increases in off-site cancer risks and noncancer hazard indices for receptor populations. Furthermore, without mitigation measures, the proposed project under Alternatives A, B, and C will result in exceedances of regulatory thresholds for criteria and/or toxic pollutants. (SEIS/EIR Table 4.24.1-3.)

At a minimum LAWA needs to: (1) develop a matrix showing each mitigation measure and how it meets each of the three missing criteria identified above; and (2) improve documentation of the effectiveness of the selected mitigation measures used to reduce pollutant emissions.

- b. Mitigation measures, except those specific to construction activities, should be applied towards the No Action/No Project alternative in addition to Alternatives A, B, C, and D.**

Mitigation measures are defined in SEIS/EIR Section 4.6.8, including Table S.4.6-18. With the exception of those measures specific to construction activities, the identified measures may be implemented under the No Action/No Project alternative as well as Alternatives A, B, C, and D. For example, the following mitigation measures identified in Table S.4.6-18 are generally applicable to all alternatives including No Action/No Project:

Airside

Convert GSE to electric power

Clean Vehicle Fleets

Promote commercial vehicles/trucks/vans using terminal areas to install SULEV/ZEV engines

Promote "best-engine" technology for rental cars using on-airport RAC facilities. Consolidate nonrental car shuttles using SULEV/ZEV technology

Energy Conservation

Cover any parking structures that receive direct sunlight to reduce volatile emissions from vehicle gasoline tanks and install solar panels on these roofs where feasible to supply electricity or hot water

Highways and Roadways

Link ITS with off-airport parking facilities, with ability to direct/divert trips to these facilities

Expand ITS/ATCS, concentrating on I- and I- corridors, extending into South Bay and Westside surface street corridors

Link LAX traffic management system with airport cargo facilities, with ability to reroute cargo trips to/from these facilities

Develop a program to minimize the use of conventional-fueled fleet vehicles during smog alerts

Landside

Contract with commercial landscapers who operate lowest emitting equipment

Parking

Provide free parking with preferential parking locations for ULEV/SULEV/ZEV in all (including employee) LAX lots; provide free charging stations for ZEV; include public outreach

Pay-on-foot (before getting into car) to minimize idle time at parking check out; include public outreach

Implement on-site circulation plan in parking lots

Promote employee rideshare opportunities

Encourage employee telecommuting

Provide video-conference facilities

Transit and Intermodal

Establish network of strategically placed, off-airport intermodal check-in terminals serviced by LAX-dedicated clean-fuel buses; provide low-priced parking to LAX users of off-airport intermodal terminal facilities; include public outreach

As noted in Part Four, Section (g), *infra*, the logical basis for evaluation of project significance under Alternatives A, B, C, or D in a future year (e.g., 2015) is the No Action/No Project alternative in the same future year. For such a comparison, it is appropriate that non-construction mitigation measures be applied towards both the build and no-build alternatives, as it is possible if not likely that these measures will be implemented regardless of which alternative is pursued. Application of non-construction mitigation measures to only the build alternatives, as is currently done, would incorrectly favor the build alternatives over the no-build alternative.

4. The Health Risk Analysis of the EIS/EIR Violate CEQA.

The flaws in the health risk analysis conducted for the EIS/EIR result in underestimated acute, cancer, and noncancer health impacts. Estimated cumulative cancer risks to school children are underestimated, cumulative cancer risks and noncancer hazards are incorrectly calculated, the significance threshold for noncancer health effects is too high, potential health impacts associated with exposure to lead are improperly calculated, potential health impact from jet engine particulate emissions are ignored, noncancer health risks to school children are underestimated, and acute health impact are not evaluated. These flaws result in an underestimation of the health impacts to receptors of concern.

- a. Alternative D with mitigation may result in a potentially significant increase in cancer risk (over baseline) to schoolchildren and/or residents in and around Lennox.**

Figure S.4.24.1-18 shows that incremental cancer risks in and around Lennox will increase under Alternative D, *even with implementation of mitigation measures*. As shown, the estimated additional (over baseline) cancer risk for residents and/or schoolchildren in the southwestern portion of Lennox is between one and ten per million individuals (dark blue shaded area). We note that the threshold of significance for incremental cancer risk is ten per million individuals. Because incremental cancer risks under Alternative D in this geographic area may be underestimated (see comment 4c), actual incremental cancer risks may exceed the threshold of significance.

- b. Incremental cancer and noncancer risks in the area northeast of the I-105/I-405 Interchange may be underestimated under all project alternatives.**

The EIS/EIR may underestimate cancer and noncancer risks to residents and schoolchildren in the area northwest of the I-105/I-405 interchange. Actual airborne concentrations of carbon monoxide and toxic air contaminants including benzene, 1,3-butadiene, formaldehyde, and diesel exhaust in areas downwind from the I-105 and I-405 highways may be higher than estimated in the EIS/EIR because (1) pollutant emissions from motor vehicles may not be completely accounted for in the analysis (see comment 2b) and (2) the effect of buildings and other structures on air flow and buildup of pollutant concentrations may not have been adequately considered (comment 2c).

- c. Estimated cumulative cancer risks to school children have been underestimated due to underestimates in the total number of years children spend in school.**

The *Human Health Risk Assessment* (HHRA) estimated the potential incremental cancer risks for children attending schools by identifying the school with the highest projected concentrations of toxic air pollutants, and determining the total length of time that children would likely be at school. Approximately 20 schools were identified as being within one mile of LAX. Lennox Middle School was identified as a location where high cancer risks to school children are predicted to occur. (SDEIS/EIR, *Technical Report 9a*, Attachment B, Figures B-1 and B-2.)

Children ages 6 to 12 years old were evaluated in the HHRA, since "this age range includes the youngest school ages and it is sufficiently long for analysis of chronic exposures and risks" (Original EIS/EIR, *Technical Report 14a*, Attachment B, p. 42). Accordingly, children in school were assumed to be exposed to emissions from LAX for six years.

However, given that children will, in fact, be in school from ages 5 to 18 years (kindergarten through 12th grade), and that one charter high school currently exists within Lennox and another is being planned, it is very likely that children could be exposed to emissions from LAX for a 13-year period (corresponding to kindergarten through 12th grade). As estimates of cancer risk are directly proportional to the total time that an individual is exposed over the course of the lifetime, the assumption that school children are only exposed for six years is misleading, and results in an underestimate of the potential incremental cancer risks posed by children attending school.

Cancer risks for school children are underestimated in the EIS/EIR. Cancer risks should be recalculated for the school children to account for the potential that children could be exposed to emissions from LAX during their entire pre-school through high school years.

d. Significant flaws in the methods used to calculate cumulative cancer risks and noncancer hazards undermine the conclusions of the EIS/EIR and obscure actual health risks posed by the various alternatives.

The HHRA repeatedly touts the benefits of all build alternatives, stating that with mitigation, “all of the build alternatives would have lower (more favorable) human health impacts than those associated with the No Action/No Project Alternative . . .” (Original EIS/EIR, p. 4-999.) Many of the tables and text describing the incremental cancer risks and noncancer hazards actually present negative risks, indicating not only a reduction in risks below those associated with baseline conditions, but a “beneficial impact on LAX-associated cancer risks” (or noncancer hazards). (Original EIS/EIR, *Technical Report 14a*, p. 51.) Such statements are not only misleading, they are technically inaccurate.

For example, some of the projected increase in cancer risk for some chemicals for Alternative D 2015 pre-mitigation conditions (e.g., diesel particulates, formaldehyde, benzene) is claimed to be offset by a projected decrease in cancer risk for other chemicals (arsenic, beryllium, and chromium). (SEIS/EIR, *Technical Report 9a*, Table S8.)

The fundamental flaw in this logic is the assumption that a decrease in the concentration of one carcinogenic compound can offset the increase the concentration of another carcinogen. If the implementation of a given alternative results in lower concentrations of diesel exhaust than would occur under the baseline conditions, then the incremental contribution of diesel to the total cancer risk drops to zero. However, a net reduction in diesel is not “credited” against the likelihood that increases in other chemicals may cause cancer in exposed individuals.

To illustrate this point, assume two chemicals exist, say 1,3-butadiene and benzene, and the baseline cancer risks are 10×10^{-6} for each chemical. If the projected cancer risk under Alternative A is 13×10^{-6} for 1,3-butadiene and zero for benzene, the projected incremental cancer risk is $+3 \times 10^{-6}$ for 1,3-butadiene and the projected incremental cancer risk from benzene would be presented as -10×10^{-6} (indicating that the concentrations of benzene under Alternative A drop below the baseline concentrations), the cumulative risk from both compounds is NOT -7×10^{-6} , as would be presented in this HHRA, it is 13×10^{-6} . Independent of any projected improvement in diesel risks, 1,3-butadiene is still projected to cause an increase in cancer risk of $+3 \times 10^{-6}$.

In other words, if the projected incremental cancer risk posed by 1,3-butadiene is $+3 \times 10^{-6}$ and the projected incremental cancer risk from diesel is presented as -14×10^{-6} (indicating that the concentrations of diesel under the alternative drop below the baseline concentrations), the cumulative risk from both compounds is NOT -11×10^{-6} , as presented in this HHRA, it is $+3 \times 10^{-6}$. Independent of any projected improvement in diesel concentrations, 1,3-butadiene is still projected to cause an increase in cancer risk of 3×10^{-6} . (Data values taken from Original EIS/EIR, *Technical Report 14a*, Table 13, Alternative A, Adult Resident.)

Potential health impacts have been improperly summed. This fundamental flaw permeates the HHRA, and results in underestimates of the potential health impacts of all alternatives. As currently presented, it is impossible to evaluate each of the alternatives to determine which alternatives may pose a significant health threat, or to ascertain whether the proposed mitigation measures will be sufficient to reduce the health risks to insignificant levels.

The Lennox School District recommends that LAWA correct these errors and recalculate the risks for all alternatives.

- e. The basis for significance threshold for noncancer health effects is unclear and five times greater than the threshold typically used by regulatory agencies.**

A significant impact relative to human health is defined in the Original EIS/EIR as a build alternative that would result in a total incremental chronic hazard index (HI) greater than 5 for any target organ system at any receptor location. (Original EIS/EIR, p 4-1009.) The basis for this significance threshold is unclear, is inconsistent with statements made in the *Human Health Risk Assessment Technical Report*, and is considerably less protective than acceptable thresholds established by regulatory agencies under various regulatory programs.

As described in the Original EIS/EIR, noncancer risk estimates are calculated by dividing the estimated exposure by the “reference dose,” often referred to as the acceptable exposure level. (Original EIS/EIR, *Technical Report 14a*, p 28.) The ratio of the exposure to the reference dose is termed the hazard quotient (HQ). To assess the overall potential for noncarcinogenic effects posed by more than one chemical, the HQs for each chemical are summed, and the resulting value is referred to as the Hazard Index (HI).

As stated in the Original EIS/EIR, “a HQ greater than one indicates an exposure greater than that considered safe . . .” (Original EIS/EIR, *Technical Report 14a*, p. 28.) This conclusion is consistent with thresholds established by USEPA and Cal/EPA under the *Comprehensive Environmental Response, Compensation, and Liability Act* (CERCLA), and California’s Toxic Hot Spots program (AB2588), respectively. Similarly, an overall HI of no greater than one is the threshold that is used by Cal/EPA in determining whether conditions at a site could potentially result in unacceptable adverse noncancer health effects. Sites for which the multichemical HI is greater than one typically trigger further investigation, and often remediation.

The significance threshold used in this EIS/EIR to evaluate the potential for adverse noncancer health effects is five times higher (i.e., five time less protective) than noncancer thresholds typically used by regulatory agencies under various state and federal regulatory programs. It is unclear how and why a different and less protective standard is being used to evaluate the potential health impacts associated with the various build alternatives. If the more standard noncancer HI threshold of one were used to evaluate the significance of the various alternatives, the conclusions of each of the build alternatives, and the corresponding need for mitigation, would be different than is currently presented.

For example, under Alternative B in 2015, “people living in an area immediately east of the north runways might be exposed to TAPs from LAX sufficiently to produce a hazard index above [5]. People living in a larger area extending east-northeast from the LAX theme building over 6 miles would be exposed to sufficient concentrations of TAPs to produce an incremental hazard index between 1 and 5 . . .” (Original EIS/EIR, p. 4-1014.) Thus, the number of people subjected to unhealthy levels of toxic chemicals may be greatly understated by the EIS/EIR.

The effect that establishing the threshold hazard index at 1 would have on the conclusions of the Alternative D analysis is unclear. The Lennox School District has commented elsewhere that the manner in which incremental risks under the project build alternatives are calculated and expressed in the EIS/EIR is inappropriate (i.e., use of negative risks, selection of 1996 as baseline, methodology for calculating baseline risks). If Alternative D risks were redefined and recalculated as suggested, and if the threshold index were established at 1 per standard practice, then estimated noncancer risks may exceed the significance threshold.

The discussion of noncancer risks is critical because children are more susceptible to noncancer risks as a result of the rapid growth and development of their nervous, immune and reproductive systems, and rapid maturing organs and tissues. Noncancer risks to children include, but are not limited to, increases in asthma and other respiratory related illness such as pulmonary bacterial infection, emphysema, chronic bronchitis, and reduced pulmonary function. As discussed in Part One, Section 2c, Lennox School District students are the most exposed to LAX-related pollution, and appear to have the highest asthma rate, of any population in the Los Angeles area.

LAWA should rewrite the discussion of noncancer risks, and clearly identify those alternatives that would be considered significant based on the more appropriate noncancer significance threshold of one.

f. The EIS/EIR fails to consider and evaluate the potential health impacts associated with exposure to lead.

As described in the EIS/EIR, lead "may be released in significant quantities from LAX . . ." (Original EIS/EIR, *Technical Report 14a*, Attachment B, p. 19.) The potential impacts associated with exposure to lead are typically evaluated by using models developed by both USEPA and Cal/EPA to predict the blood-lead level that would result from a given exposure.

Because children are especially sensitive to the neurological effects of low levels of lead exposure, these models are used to estimate the blood-lead levels in children. The results from the model are then compared to the low blood-lead levels that have been demonstrated to result in subtle neurological damage in children, as established by the Center for Disease Control (CDC). The models are easy to use, have been used for more than eight years, and are considered the industry standard for evaluating lead exposures and determining whether such exposures could result in unacceptable health impacts.

Although the EIS/EIR notes that LAX may release significant quantities of lead, the EIS/EIR does not evaluate the impacts of such releases in accordance with the standard industry practice. Instead, the EIS/EIR compares the predicted concentrations of lead to the Ambient Air Quality Standard, and concludes that, because the concentrations are below the Ambient Air Quality Standard, lead is not a toxic air pollutant (TAP) of concern for the LAX Master Plan. (Original EIS/EIR, *Technical Report 14a*, Attachment B, p. 12.)

Such treatment of lead significantly diminishes the public health significance of this TAP, and does not allow for a fair determination as to the public health impacts that may result from the various build alternatives. Any risk assessment submitted to either Cal/EPA or the USEPA would be instantly rejected if conclusions about the public health significance of lead were based solely on a comparison to the Ambient Air Quality Standard.

Further, the EIS/EIR states that a cancer slope factor is not available for lead. (Original EIS/EIR, *Technical Report 14a*, Attachment B, pp. 18-19.) The Lennox School District notes that the Cal/EPA Office of Environmental Health Hazard Assessment (OEHHA) has released a cancer slope factor for lead. The cancer slope factor, although not yet a promulgated standard, is available, and is being used by OEHHA to establish the No Significant Risk Level (NSRL) for lead under California's Proposition 65.

Health impacts resulting from lead in all years/scenarios, including Alternative D, may be underestimated. Because of the heightened public awareness to the risks associated with lead exposure and the plethora of information that exists describing the adverse health effects that can result from lead exposure, lead should be evaluated in this EIS/EIR in the most comprehensive manner that is reasonably practicable. Failure to do so is scientifically unjustifiable and is inconsistent with the more rigorous evaluations conducted for other chemicals included in the HHRA.

LAWA should rerun all health risk calculations to determine the human health implications of the increases in lead emissions that will result from all build alternatives.

- g. Excluding particulate emissions from jet aircraft from the quantitative risk evaluation could significantly underestimate the potential for noncancer health impacts.**

Particulate emissions from aircraft were not quantified in the HHRA because "there is insufficient information regarding the nature and toxicity of total petroleum hydrocarbon (TPH) emissions associated with aircraft and toxicity criteria for these emissions are not available . . ." (Original EIS/EIR, *Technical Report 14a*, p. 81.) Particulate matter, in the form of diesel exhaust, is emitted from several ground sources (predominantly trucks and buses). Emissions of diesel exhaust from these ground sources have been included in the HHRA. However, the EIR states that because aircraft use a different fuel and a substantially different combustion process than diesel engines, the particulate emissions in jet exhaust are "not considered chemically, physically, or toxicologically similar to diesel exhaust . . ." (Original EIS/EIR, *Technical Report 14a*, p. 12.) Accordingly, the impact of such emissions have not been quantified in the HHRA.

This is the logic set forth in the EIS/EIR for excluding jet particulate emissions from the HHRA. The argument, however, for not being able to evaluate the toxicological effects of particulate exhaust from jets is flawed. Functionally, the methods used to evaluate the noncarcinogenic toxicity of "diesel" are based entirely on the particulate matter present in diesel exhaust.

According to USEPA, the systemic (non-cancer) toxicity of diesel emissions is due to the insoluble carbon core of diesel particles; when the exhaust is filtered to remove the particulate matter, the remaining exhaust mixture does not produce long-term toxicological effects in laboratory animals. The mechanism of toxicity of the carbon core relates to the deposition of the particles deep in the lung, and the accumulation and aggregation of these particles that result from the inability of the lung's normal clearance mechanisms to effectively remove the particles from the deep regions of the lung. The accumulation of particles sets off a pathogenic sequence that may result in the presence of pulmonary inflammatory, fibrotic, or emphysematous lesions. (United States Environmental Protection Agency (USEPA), *Integrated Risk Information System*, On-line database maintained by USEPA, 2001.)

Because the noncancer toxicity associated with diesel exhaust is believed to be attributable entirely to the insoluble carbon core of the particulate matter, the noncancer toxicity factor would be equally applicable to other sources of particulate matter, such as jet fuel exhaust. If one can estimate the quantity of particulate matter that could be released from the exhaust of a jet engine, then use of the noncarcinogenic toxicity criteria for diesel is a scientifically defensible and appropriate method for evaluating the public health significance of the particulate emissions. Given the significant increase in the air traffic at LAX, failure to quantify potential impact associated with particulate emissions from jet aircraft could represent a significant omission from the estimated noncancer impacts.

The fact that particulate emissions from aircraft engines may be different than those from diesel engines is not adequate justification for ignoring the cancer health risks of aircraft particulate emissions entirely. It is reasonable to assume, given the lack of information to the contrary, that aircraft particulate emissions *are* similar to diesel emissions with respect to cancer effects. If this assumption were false, and aircraft particulates were in fact less carcinogenic than diesel exhaust, then the result would represent a conservative upper bound of the cancer risk posed by aircraft particulate matter. The existing estimate of risk posed by aircraft particulates, i.e. zero, could be considered a lower bound.

Data presented in Attachment W to *Technical Report 4* of the Original EIS/EIR indicate that aircraft contribute approximately 45 percent of total LAX operational PM₁₀ emissions within the LAX local area. If one makes the assumption that the cancer and noncancer toxicity of aircraft PM₁₀ emissions are similar to that of diesel particulates, they would conclude that the cancer and noncancer risks posed by operational PM₁₀ emissions may be underestimated by roughly a factor of 2 in all years/alternatives. The relative contributions of particulate matter to total cancer and noncancer risks in different years/alternatives are not presented in the SEIS/EIR. (See Part Four, Section 4g., *infra*.)

Health impacts from particulate matter may be underestimated. The Lennox School District recommends that LAWA recalculate all estimates of noncancer risk, and include in the evaluation the potential adverse health effects that can result from exposure to particulate emissions from jet aircraft.

h. Absolute cancer and noncancer risks are not presented in the EIS/EIR.

Cancer and noncancer risks are quantified solely on an incremental basis relative to 1996 risks, which themselves are not presented. The impression received is that presentation of absolute risk numbers is being avoided, presumably because they are large and may cause alarm.

- i. The EIS/EIR does not consider child-specific noncancer toxicity criteria which have been proposed by the State of California and are intended for use in the risk assessment of California school sites. Noncancer health risks to schoolchildren may be underestimated accordingly.**

Cal/EPA has issued proposed child-specific chronic reference doses (chRfDs) for six chemicals of particular concern to the health of schoolchildren: cadmium, chlordane, heptachlor, heptachlor epoxide, methoxychlor, and nickel (Cal/EPA, *Development of Health Criteria for School Site Risk Assessment Pursuant to Health and Safety Code Section 901(g): Proposed Child-Specific Reference Doses (chRfDs) for School Site Risk Assessment - Cadmium, Chlordane, Heptachlor/Heptachlor Epoxide, and Nickel*. Draft Report. Integrated Risk Assessment Section, Office of Environmental Health Hazard Assessment, June 2003, Exhibit 29). The proposed child-specific RfDs are generally more conservative than the US EPA RfDs used in the EIS/EIR health risk assessment, as shown in the following table.

Chemical	Proposed chRfD (mg/kg-d)	USEPA RfD (mg/kg-d)	Ratio
Cadmium	1 x 10 ⁻⁵	5 x 10 ⁻⁴	50
Chlordane	3.3 x 10 ⁻⁵	5 x 10 ⁻⁴	15
Heptachlor	3 x 10 ⁻⁵	5 x 10 ⁻⁴	17
Heptachlor epoxide	1.3 x 10 ⁻⁵	1.3 x 10 ⁻⁵	1
Methoxychlor	2 x 10 ⁻⁵	5 x 10 ⁻³	250
Nickel	3.7 x 10 ⁻³	2 x 10 ⁻²	5

The proposed chRfDs were developed by Cal/EPA specifically for the protection of schoolchildren and are intended for use in the risk assessment of California school sites. Thus, these toxicity criteria are appropriate for use in the EIS/EIR health risk analysis of noncancer impacts to offsite school children.

As the relationship between reference dose and noncancer health risk (hazard quotient) is linear, use of these chRfD values would result in an increase in the estimated noncancer health risk to school children from each of the listed chemicals, by the amount (ratio) given in the table. For example, the estimated noncancer health risk to school children posed by cadmium would be 50 times greater if the chRfD value were used.

Only one of the six listed chemicals is identified as a chemical of potential concern (COPC) in the EIS/EIR health risk assessment: cadmium. However, use of these RfD values may cause additional chemicals to be added to the group of COPCs. For example, an increase in the estimated health risk from methoxychlor by a factor of 250 may elevate this chemical to the status of potential concern.

At a minimum, the EIS/EIR health risk analysis should consider these toxicity criteria in an uncertainties section, and assess to what extent adoption of these criteria would affect the conclusions of the health risk assessment.

j. Use of 1996 as basis for determining project significance is not explained and seems illogical.

Significance of project impacts under build scenarios in future years is evaluated by comparison to 1996 "baseline" conditions and, in the SEIS/EIR, to 2000 conditions. The rationale for this is not clear. To evaluate project impacts for, e.g., Alternative D in 2015, it seems more logical to compare Alternative D 2015 conditions to No Action/No Project 2015 conditions. In this manner, the effects of the project may be directly quantified.

k. Methodology for establishment of baseline (1996) impacts is poorly defined and highly suspect. All determinations of significance of Alternative D through comparison to 1996 baseline impacts are therefore questionable.

According to the Original EIS/EIR, 1996/baseline impacts were not estimated directly but rather were derived by adjusting model predictions under the 2005 no-build alternative:

"Baseline conditions were not separately modeled. Instead, air quality for the baseline year (1996) was estimated from results of air dispersion modeling for the No Action/No Project Alternative for horizon year 2005...Thus, emissions estimates for 1996 were derived by subtracting out emissions associated with the No Action/No Project Alternative in 2005. . ." (Original EIS/EIR, p. 4-1007).

The Lennox School District notes that the 1996 emissions inventory is the basis for all other inventories, including the 2005 No Action/No Project Alternative inventory, and therefore assumes that the final sentence in the above citation is a misstatement. It infers that 1996/baseline chemical concentrations were derived by scaling the chemical concentrations predicted by the air dispersion model for the 2005 No Action/No Project Alternative. The EIS/EIR does not document or support this scaling operation. The Lennox School District is unaware of any way in which a modeled concentration field may be scaled other than by uniform application of a constant factor (all values in a given chemical concentration field multiplied by the same factor). Therefore, it appears that any source-specific (i.e., spatial) differences between the 1996 and 2005 inventories were lost in the scaling process.

The EIS/EIR does not explain or support the rationale for not simply estimating baseline impacts directly, by using the 1996 inventory as input to the dispersion model. The indirect method apparently employed is inferior to direct modeling of 1996 impacts, because it results in a loss of spatial resolution of chemical emissions and resulting airborne concentrations. As the 1996/baseline impacts are the basis for determination of significance of the project, the process by which these baseline impacts were estimated should be thoroughly described. From the sparse and confusing discussion provided, it appears that the 1996 impacts were roughly fudged. Therefore, the Lennox School District holds significance determinations based on these 1996 impacts to be generally questionable.

l. Alternative D post-mitigation incremental cancer risk to adult residents may be greater than 10 per million individuals.

Table S4.24.1-5 of the SEIS/EIR indicates that the post-mitigation incremental cancer risk to adult residents is 2 per million individuals, below the significance threshold of 10 per million individuals. However, given that (see other comments) (1) cancer risk posed by secondary pollution is ignored, (2) cancer risk posed by aircraft particulate matter is ignored, (3) cancer risk posed by lead is ignored, and (4) the 1996 baseline cancer risk is highly suspect, the actual Alternative D post-mitigation incremental cancer risk may exceed the significance threshold of 10 per million individuals.

m. Statement that acrolein noncancer risks are substantially overestimated in the EIS/EIR analysis is not supported by the arguments presented.

"Emissions estimates for acrolein are based on available data that were generated from old aircraft engines not generally in use today and using military fuel that differs from fuel used at LAX . . ." (SEIS/EIR, *Human Health Risk Assessment*, p. 4-615.) This statement implies that newer aircraft using civilian fuel emit less acrolein than estimated. However, the implication is not supported by any other information.

"Acrolein is not generally recognized as a significant TAP in the South Coast Air Basin . . ." (p. 4-615.) Prior recognition is not relevant or required. Further, this statement is contradicted by results of the USEPA study, which suggest that "hazard indices might fall in the range of 3 to 10 for chronic exposure to acrolein . . ." (SEIS/EIR, *Human Health Risk Assessment*, p. 4-619.)

"A recent study near Chicago's O'Hare Airport failed to detect acrolein in essentially all samples taken in communities near the facility . . ." (SEIS/EIR, *Human Health Risk Assessment*, p. 4-615.) Without discussion of sampling and analysis methods, especially of comparison of method detection limits to levels of concern, this statement is meaningless.

"The analysis presented for acrolein in the HHRA may substantially overestimate releases, and thus may overestimate possible chronic and acute impacts to human health . . ." (SEIS/EIR, *Human Health Risk Assessment*, p. 4-615.) For the reasons noted above, the Lennox

School District does not believe that sufficient evidence is presented in the EIS/EIR to justify this statement that acrolein impacts are overestimated in the HHRA.

n. Use of different receptor/grid spacing when calculating pre- and post-mitigation impacts prevents assessment of mitigation effectiveness.

“A greater number of endpoints were assessed for post-mitigation conditions than for pre-mitigation conditions to ensure that the highest post-mitigation impacts were identified. As such, post-mitigation risks and hazard estimates represent conservative estimates which are in some cases greater than pre-mitigation risks . . .” (SEIS/EIR, *Human Health Risk Assessment*, p. 4-617.)

Increasing the receptor density does not *ensure* that the highest post-mitigation impacts are identified, it only increases the likelihood that they are identified. The additional data points likely include both lesser and greater values than would be predicted if only the smaller number of endpoints were considered. With both endpoint sets, it is possible, if not likely, that the greatest impacts (highest risk values) are not identified; however, this possibility is lower for the larger, post-mitigation endpoint set.

As noted, estimated post-mitigation risks in some cases are higher than pre-mitigation risks. This apparent increase in risk is likely an artifact caused by the larger number of endpoints used in the post-mitigation modeling. Comparison of pre- and post-mitigation impacts should be made with the same endpoint set (i.e., same group of receptors), to measure mitigation effectiveness.

PART FIVE

THE TRAFFIC IMPACT ANALYSIS IS INADEQUATE

To address traffic impacts of Alternative D on the Lennox School District, the SEIS/EIR must identify those locations where project traffic could cause significant impacts. (14 *California Code of Regulations* 151064.) In this regard it is typical for a traffic study to have clearly defined performance criteria with respect to how the study area is defined and the definition of “significant impact” within that study area. While the study area has been expanded since the Original EIS/EIR, it is not clear whether the expanded area of impact within the Lennox School District has been selected in this manner. Even if the impacts are less than significant, the SEIS/EIR should contain an evaluation showing how the study area was selected and indicating findings of significance or no significance on roadways within the Lennox School District.

Additionally, significant impacts to Lennox School District of the Lennox Interchange are not identified or addressed. CEQA requires evaluation in the SEIS/EIR of the significant impacts of the *mitigation measures of projects* as well as the project itself. (14 *California Code of Regulations* 15126.4.) The SEIS/EIR fails to do so.

1. The Analysis of the Impacts of the Lennox Interchange is Inadequate.

The addition of an interchange with I-405 at Lennox Boulevard is being proposed as a mitigation measure for Alternative D. The secondary impacts of this interchange on the Lennox street system needs to be studied since the addition of this interchange will have a number of direct and indirect effects on the Lennox area. (*Id.*) The most important of these are as follows:

- a. Street closures may affect children's walk-to-school routes and create safety concerns for children walking to and from school.**

The closure of Lennox Boulevard just east of the I-405 will divert traffic to parallel streets such as Century Boulevard and Imperial Highway, both of which serve the Lennox area. The resulting changes in traffic patterns relative to walk-to-school routes need to be assessed. For example, children may face more traffic and therefore may be exposed to increased safety risks in their walk-to-school routes. The SEIS/EIR should examine these issues and also possible mitigation measures to ensure safe walk-to-school routes (ex. crossing-guards, visibility improvements for intersections, etc.)

- b. Configuration of entrance and exit freeway ramps will necessitate relocation of a Lennox School District preschool.**

The SEIS/EIR fails to mention an existing preschool located on Lennox School District property. The Lennox interchange contemplates two alternatives for the erection of a freeway entrance and freeway exit loop ramp. Although the selection between these two alternatives will not be made until the Caltrans Project Study Report (PSR) process is completed, the preschool will be affected by one of these alternatives. In short, one of the alternatives will necessitate the relocation of the preschool. This impact and relocation concerns must be addressed in the SEIS/EIR.

- c. The construction impacts of the Lennox Interchange must be examined.**

The construction impacts of this interchange could be significant, especially for Buford Elementary School and Lennox Middle School, just west of Buford Avenue, and Felton Elementary School west of Felton Avenue. Construction phasing, and traffic management plans for construction traffic need to be studied to ascertain the type and magnitude of such impacts.

2. Traffic Impacts of Alternative D on the Lennox School District Are Not Properly Addressed.

There are numerous other issues related to the impact of Alternative D on the Lennox area and hence on the Lennox School District. Alternative D expands the airport complex to the east, and although the I-405 Freeway acts somewhat as a barrier with respect to direct impacts in Lennox, there is the potential for indirect impacts that are either not addressed or only briefly addressed in the SEIS/EIR. Some examples are as follows:

- a. **Impacts of freeway avoidance traffic on Lennox School District are inadequately addressed.**

Most of the freeway and freeway access mitigation measures will need to be the subject of further analysis as Caltrans Project Study Reports are prepared and more detailed designs are formulated. There is no assurance that desired freeway levels of service will be achieved when both project and cumulative impacts are considered. Under such conditions, "freeway avoidance" traffic could impact local streets and some of that freeway avoidance traffic will include airport trips (primarily employee and service related trips rather than air passenger trips). Actual conditions on the Lennox street system could therefore be worse than portrayed in the SEIS/EIR. Ideally, some provision should be made for monitoring traffic conditions to determine the magnitude of such trips, and to establish some form of "second tier" list of improvements for locations that may be impacted in this manner with trigger points for implementing improvements.

- b. **Construction impacts on traffic in Lennox are inadequately addressed.**

The SEIS/EIR discusses construction traffic routing as a mitigation measure for project construction. The Lennox School District should be involved in this process in reviewing construction traffic routing to ensure that minimum impacts occur to schools, particularly the three schools located in the western part of the District.

- c. **Impacts to Lennox associated with phasing of transportation improvements are inadequately addressed.**

The phasing of transportation improvements is an important issue. Traffic impacts in the AM peak hour are of particular importance. Congested locations during this time will both impede students traveling to school, and cause secondary impacts such as traffic diverting to neighborhood streets to avoid congestion. Some discussion is given in the SEIS/EIR based on a conceptual phasing plan for the Master Plan. That phasing will be a complex undertaking, and should be accompanied by a detailed disclosure of impacts and mitigation measures for each phase as the details of the phasing plan emerge. Lennox's close proximity to the airport makes it vulnerable to any situation in which unanticipated traffic impacts of a particular phase causes problems on the local street system. Such impacts could well exceed those identified for the 2008 and 2015 time frames in the SEIS/EIR.

PART SIX

THE ENROLLMENT IMPACT ANALYSIS IS INADEQUATE

The SEIS/EIR discusses the impact of Alternative D on enrollment as follows:

"Due to productivity increases (i.e., the production of more economic output per worker), Alternative D would result in a decrease of approximately 2,657 on-airport employees within the schools study area by 2015. As each on-airport employee is

assumed to represent one household, the number of on-airport employee households within the schools study area would, therefore, decline by approximately 2,657." (SEIS/EIR, *Schools*, Section 4.27, p. 4-764.)

As to student enrollment for the Lennox School District, the SEIS/EIR states that in addition to Los Angeles Unified School District (LAUSD), "31 other school districts throughout Los Angeles County would also experience indirect project-related enrollment declines." However, the SEIS/EIR does not provide an estimate of the Lennox School District's expected share in decreased enrollment.

Without an analysis of Lennox School District enrollment in the SEIS/EIR, the impact to Lennox School District is unknown, but may very well be significant. The SEIS/EIR should assess the enrollment impact to Lennox School District and mitigate accordingly.

Whether the decrease in students is only relatively small to other school districts, the impact on the Lennox School District will be substantial. The Lennox School District relies almost exclusively on Average Daily Attendance for its revenue. A loss of students means the loss in student generated revenue. These impacts would translate into significant impacts upon budgeting, employment, maintenance and operations within the Lennox School District, and *must* be studied further, so that mitigation measures can be developed to address these impacts.

PART SEVEN

THE SUBSTANTIAL SHIFT IN PROJECT OBJECTIVES REQUIRES LAW TO EXAMINE AN ADEQUATE RANGE OF PROJECT ALTERNATIVES

Following the events of September 11th terrorist attacks, the basic objectives of the project have significantly shifted to an emphasis on security and safety over expansion. Several statements have been attributed to Mayor Hahn to this effect. However, Mayor Hahn's new objectives are only addressed in one alternative, Alternative D, the only alternative admittedly focused on enhanced safety and security measures.

The 1998 amendments to the CEQA Guidelines emphasized the importance of a clearly written statement of objectives. The following language was added for the requirements of the "project description,"

"A clearly written statement of objectives will help the lead agency develop a reasonable range of alternatives to evaluate in the EIR and will aid the decision makers in preparing findings or a statement of overriding considerations, if necessary. The statement of objectives should include the underlying purpose of the project."
(14 *California Code of Regulations* 15124(b).)

A discussion of this section by the Governor's Office of Planning and Research provides further insight into this amendment - "Clear project objectives simplify the selection process by providing a standard against which to measure possible alternatives."

The standard by which to judge the range of alternatives required in an EIR is governed by the "rule of reason." 14 *California Code of Regulations* 15126.6(a); *Citizens of Goleta Valley v. Board of Supervisors* (1990) 52 Cal.3d 553, 565. In this case, LAWA completely changed its focus and objectives for the LAX project, yet only set forth one alternative in the SEIS/EIR to address these objectives. By only addressing one alternative, LAWA has effectively limited the public from meaningful public participation and informed decision making. It precludes the option of selecting a project that addresses the safety and security concerns of LAWA with less of an accompanying environmental justice impact. The notable lack of alternatives does not permit a reasoned choice and does not withstand the CEQA's "rule of reason."

When LAWA presented a 180 degree shift in its basic and central objectives, LAWA was required to comply with CEQA by discussing a reasonable range of alternatives. LAWA's failure to do so is fatal to the SEIS/EIR.

PART EIGHT

THE EIS/EIR VIOLATES CEQA READABILITY REQUIREMENTS

California Public Resources Code § 21003 states, in pertinent part:

"The Legislature further finds and declares that it is the policy of the state that:

"(b) Documents prepared pursuant to this division be organized and written in a manner that will be meaningful and useful to decision makers and to the public. . .

"(f) All persons and public agencies involved in the environmental review process be responsible for carrying out the process in the most efficient, expeditious manner in order to conserve the available financial, governmental, physical and social resources with the objective that those resources may be better applied toward the mitigation of actual significant effects on the environment."

Both the Original EIS/EIR and the SEIS/EIR violate this Code section.

a. Original EIS/EIR.

The Original EIS/EIR is inaccessible. It is 12,000 pages long and costs thousands of dollars to purchase. The CD version, although less expensive, is only accessible to people with computers. Many poorer residents of the most highly impacted areas do not have that

technology. Additionally, the CD version contains many glitches, so entire sections are impossible to read or print. (See, e.g., EIS/EIR, CD Version *Technical Report 4*.)

Second, the Original EIS/EIR is so poorly organized that it is nearly impossible to find all of the pertinent information regarding a topic. Analysis regarding a particular topic is often spread among numerous sections of the "main document." Several of the so-called "technical reports" contain substantive narrative that is not reflected in the report itself. The "appendices" often contain other important information. The document itself provides no logical explanation as to why its contents are distributed in this manner.

For instance, as expected, the *Noise* section of the Original EIS/EIR contains information regarding the noise impacts of LAX expansion upon Lennox School District schools. However, the *Noise Technical Report*, thousands of pages later, contains crucial noise impact information that is entirely absent from the *Noise* section of the main document. In addition, the *Noise Technical Report* is not contained on the CD entitled "Technical Reports". Instead, it is on the "Appendices" CD, and is actually Appendix "D". The reason for this is entirely unclear.

The *Land Use* section, a thousand pages from the *Noise* section and several thousand pages from the *Noise Technical Report*, essentially states that LAWA will not mitigate noise impacts identified in the *Noise* section. (EIS/EIR, *Land Use*, Section 4.2, pp. 4-95, 4-96.) These few, critical sentences are not contained in the *Noise* section of the main document, nor the *Noise Technical Report*. This illogical placement of this crucial language suggests an intentional decision to obscure information that would raise "red flags" in respondents.

b. Addition of Supplement to the EIS/EIR.

The SEIS/EIR contains many of the same problems of the Original EIS/EIR. It is thousands of pages long and costs over a thousand dollars to purchase. Consistent with the Original EIS/EIR, the various *Supplemental Noise Technical Reports* and the *Environmental Justice Technical Report* are contained in the "Appendices" rather than with the "Technical Reports," as would make sense. Although the CD version of the document is less expensive, it is not accessible to those impacted citizens of Lennox who do not have access to a computer and are not trained to utilize the complex programs required to read from the CDs.

In total, the EIS/EIR violate CEQA readability requirements, and are inaccessible to a significant portion of the population impacted by the project that is the subject of the EIS/EIR.

CONCLUSION

The individual and cumulative impacts of the EIS/EIR, including Alternative D, upon the education, health and safety of its students are of substantial concern to the Lennox School District. By law, LAWA must adequately consider and mitigate these impacts in its EIS/EIR. It fails to do so.

The EIS/EIR fails to adequately analyze the environmental justice, noise, health, pollution, traffic and enrollment impacts of the proposed project upon the Lennox School District. The EIS/EIR fails to propose adequate mitigation measures for these impacts. Furthermore, the EIS/EIR analysis of the cumulative impacts of the LAX expansion upon the Lennox School District is inadequate, both due to its own insufficiency and due to the inadequacy of its analyses of the underlying impacts.

For the foregoing reasons, the Lennox School District respectfully requests that LAWA revise the EIS/EIR to include alternative projects, further impact analysis and site specific mitigation information and proposals regarding the impacts on the Lennox School District.

Presidential Documents

Title 3—

Executive Order 12898 of February 11, 1994

The President

Federal Actions To Address Environmental Justice in Minority Populations and Low-Income Populations

By the authority vested in me as President by the Constitution and the laws of the United States of America, it is hereby ordered as follows:

Section 1—1. Implementation.

1-101. Agency Responsibilities. To the greatest extent practicable and permitted by law, and consistent with the principles set forth in the report on the National Performance Review, each Federal agency shall make achieving environmental justice part of its mission by identifying and addressing, as appropriate, disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations in the United States and its territories and possessions, the District of Columbia, the Commonwealth of Puerto Rico, and the Commonwealth of the Mariana Islands.

1-102. Creation of an Interagency Working Group on Environmental Justice.
(a) Within 3 months of the date of this order, the Administrator of the Environmental Protection Agency ("Administrator") or the Administrator's designee shall convene an interagency Federal Working Group on Environmental Justice ("Working Group"). The Working Group shall comprise the heads of the following executive agencies and offices, or their designees: (a) Department of Defense; (b) Department of Health and Human Services; (c) Department of Housing and Urban Development; (d) Department of Labor; (e) Department of Agriculture; (f) Department of Transportation; (g) Department of Justice; (h) Department of the Interior; (i) Department of Commerce; (j) Department of Energy; (k) Environmental Protection Agency; (l) Office of Management and Budget; (m) Office of Science and Technology Policy; (n) Office of the Deputy Assistant to the President for Environmental Policy; (o) Office of the Assistant to the President for Domestic Policy; (p) National Economic Council; (q) Council of Economic Advisers; and (r) such other Government officials as the President may designate. The Working Group shall report to the President through the Deputy Assistant to the President for Environmental Policy and the Assistant to the President for Domestic Policy.

(b) The Working Group shall: (1) provide guidance to Federal agencies on criteria for identifying disproportionately high and adverse human health or environmental effects on minority populations and low-income populations;

(2) coordinate with, provide guidance to, and serve as a clearinghouse for, each Federal agency as it develops an environmental justice strategy as required by section 1-103 of this order, in order to ensure that the administration, interpretation and enforcement of programs, activities and policies are undertaken in a consistent manner;

(3) assist in coordinating research by, and stimulating cooperation among, the Environmental Protection Agency, the Department of Health and Human Services, the Department of Housing and Urban Development, and other agencies conducting research or other activities in accordance with section 3-3 of this order;

(4) assist in coordinating data collection, required by this order;

(5) examine existing data and studies on environmental justice;

(6) hold public meetings as required in section 5-502(d) of this order; and

(7) develop interagency model projects on environmental justice that evidence cooperation among Federal agencies.

1-103. Development of Agency Strategies. (a) Except as provided in section 6-605 of this order, each Federal agency shall develop an agency-wide environmental justice strategy, as set forth in subsections (b)-(e) of this section that identifies and addresses disproportionately high and adverse human health or environmental effects of its programs, policies, and activities on minority populations and low-income populations. The environmental justice strategy shall list programs, policies, planning and public participation processes, enforcement, and/or rulemakings related to human health or the environment that should be revised to, at a minimum: (1) promote enforcement of all health and environmental statutes in areas with minority populations and low-income populations; (2) ensure greater public participation; (3) improve research and data collection relating to the health of and environment of minority populations and low-income populations; and (4) identify differential patterns of consumption of natural resources among minority populations and low-income populations. In addition, the environmental justice strategy shall include, where appropriate, a timetable for undertaking identified revisions and consideration of economic and social implications of the revisions.

(b) Within 4 months of the date of this order, each Federal agency shall identify an internal administrative process for developing its environmental justice strategy, and shall inform the Working Group of the process.

(c) Within 6 months of the date of this order, each Federal agency shall provide the Working Group with an outline of its proposed environmental justice strategy.

(d) Within 10 months of the date of this order, each Federal agency shall provide the Working Group with its proposed environmental justice strategy.

(e) Within 12 months of the date of this order, each Federal agency shall finalize its environmental justice strategy and provide a copy and written description of its strategy to the Working Group. During the 12 month period from the date of this order, each Federal agency, as part of its environmental justice strategy, shall identify several specific projects that can be promptly undertaken to address particular concerns identified during the development of the proposed environmental justice strategy, and a schedule for implementing those projects.

(f) Within 24 months of the date of this order, each Federal agency shall report to the Working Group on its progress in implementing its agency-wide environmental justice strategy.

(g) Federal agencies shall provide additional periodic reports to the Working Group as requested by the Working Group.

1-104. Reports to the President. Within 14 months of the date of this order, the Working Group shall submit to the President, through the Office of the Deputy Assistant to the President for Environmental Policy and the Office of the Assistant to the President for Domestic Policy, a report that describes the implementation of this order, and includes the final environmental justice strategies described in section 1-103(e) of this order.

Sec. 2-2. Federal Agency Responsibilities for Federal Programs. Each Federal agency shall conduct its programs, policies, and activities that substantially affect human health or the environment, in a manner that ensures that such programs, policies, and activities do not have the effect of excluding persons (including populations) from participation in, denying persons (including populations) the benefits of, or subjecting persons (including populations) to discrimination under, such programs, policies, and activities, because of their race, color, or national origin.

Sec. 3-3. Research, Data Collection, and Analysis.

3-301. Human Health and Environmental Research and Analysis. (a) Environmental human health research, whenever practicable and appropriate, shall include diverse segments of the population in epidemiological and clinical studies, including segments at high risk from environmental hazards, such as minority populations, low-income populations and workers who may be exposed to substantial environmental hazards.

(b) Environmental human health analyses, whenever practicable and appropriate, shall identify multiple and cumulative exposures.

(c) Federal agencies shall provide minority populations and low-income populations the opportunity to comment on the development and design of research strategies undertaken pursuant to this order.

3-302. Human Health and Environmental Data Collection and Analysis. To the extent permitted by existing law, including the Privacy Act, as amended (5 U.S.C. section 552a): (a) each Federal agency, whenever practicable and appropriate, shall collect, maintain, and analyze information assessing and comparing environmental and human health risks borne by populations identified by race, national origin, or income. To the extent practical and appropriate, Federal agencies shall use this information to determine whether their programs, policies, and activities have disproportionately high and adverse human health or environmental effects on minority populations and low-income populations;

(b) In connection with the development and implementation of agency strategies in section 1-103 of this order, each Federal agency, whenever practicable and appropriate, shall collect, maintain and analyze information on the race, national origin, income level, and other readily accessible and appropriate information for areas surrounding facilities or sites expected to have a substantial environmental, human health, or economic effect on the surrounding populations, when such facilities or sites become the subject of a substantial Federal environmental administrative or judicial action. Such information shall be made available to the public, unless prohibited by law; and

(c) Each Federal agency, whenever practicable and appropriate, shall collect, maintain, and analyze information on the race, national origin, income level, and other readily accessible and appropriate information for areas surrounding Federal facilities that are: (1) subject to the reporting requirements under the Emergency Planning and Community Right-to-Know Act, 42 U.S.C. section 11001-11050 as mandated in Executive Order No. 12856; and (2) expected to have a substantial environmental, human health, or economic effect on surrounding populations. Such information shall be made available to the public, unless prohibited by law.

(d) In carrying out the responsibilities in this section, each Federal agency, whenever practicable and appropriate, shall share information and eliminate unnecessary duplication of efforts through the use of existing data systems and cooperative agreements among Federal agencies and with State, local, and tribal governments.

Sec. 4-4. Subsistence Consumption of Fish and Wildlife.

4-401. Consumption Patterns. In order to assist in identifying the need for ensuring protection of populations with differential patterns of subsistence consumption of fish and wildlife, Federal agencies, whenever practicable and appropriate, shall collect, maintain, and analyze information on the consumption patterns of populations who principally rely on fish and/or wildlife for subsistence. Federal agencies shall communicate to the public the risks of those consumption patterns.

4-402. Guidance. Federal agencies, whenever practicable and appropriate, shall work in a coordinated manner to publish guidance reflecting the latest scientific information available concerning methods for evaluating the human health risks associated with the consumption of pollutant-bearing fish or

wildlife. Agencies shall consider such guidance in developing their policies and rules.

Sec. 5-5. Public Participation and Access to Information. (a) The public may submit recommendations to Federal agencies relating to the incorporation of environmental justice principles into Federal agency programs or policies. Each Federal agency shall convey such recommendations to the Working Group.

(b) Each Federal agency may, whenever practicable and appropriate, translate crucial public documents, notices, and hearings relating to human health or the environment for limited English speaking populations.

(c) Each Federal agency shall work to ensure that public documents, notices, and hearings relating to human health or the environment are concise, understandable, and readily accessible to the public.

(d) The Working Group shall hold public meetings, as appropriate, for the purpose of fact-finding, receiving public comments, and conducting inquiries concerning environmental justice. The Working Group shall prepare for public review a summary of the comments and recommendations discussed at the public meetings.

Sec. 6-6. General Provisions.

6-601. Responsibility for Agency Implementation. The head of each Federal agency shall be responsible for ensuring compliance with this order. Each Federal agency shall conduct internal reviews and take such other steps as may be necessary to monitor compliance with this order.

6-602. Executive Order No. 12250. This Executive order is intended to supplement but not supersede Executive Order No. 12250, which requires consistent and effective implementation of various laws prohibiting discriminatory practices in programs receiving Federal financial assistance. Nothing herein shall limit the effect or mandate of Executive Order No. 12250.

6-603. Executive Order No. 12875. This Executive order is not intended to limit the effect or mandate of Executive Order No. 12875.

6-604. Scope. For purposes of this order, Federal agency means any agency on the Working Group, and such other agencies as may be designated by the President, that conducts any Federal program or activity that substantially affects human health or the environment. Independent agencies are requested to comply with the provisions of this order.

6-605. Petitions for Exemptions. The head of a Federal agency may petition the President for an exemption from the requirements of this order on the grounds that all or some of the petitioning agency's programs or activities should not be subject to the requirements of this order.

6-606. Native American Programs. Each Federal agency responsibility set forth under this order shall apply equally to Native American programs. In addition, the Department of the Interior, in coordination with the Working Group, and, after consultation with tribal leaders, shall coordinate steps to be taken pursuant to this order that address Federally-recognized Indian Tribes.

6-607. Costs. Unless otherwise provided by law, Federal agencies shall assume the financial costs of complying with this order.

6-608. General. Federal agencies shall implement this order consistent with, and to the extent permitted by, existing law.

6-609. Judicial Review. This order is intended only to improve the internal management of the executive branch and is not intended to, nor does it create any right, benefit, or trust responsibility, substantive or procedural, enforceable at law or equity by a party against the United States, its agencies, its officers, or any person. This order shall not be construed to create any right to judicial review involving the compliance or noncompliance

of the United States, its agencies, its officers, or any other person with this order.

--	--

Enrollments in California schools have been steadily increasing for more than 15 years, though the pace has slowed lately and is expected to level off in the middle of this decade. The percentage of Hispanic students has steadily grown (they are expected to form the majority by 2009-10) while African-American and white students have declined. Remaining fairly constant is the percentage of students from Asia, the Pacific Islands, and the Philippines. A continuing trend is the increase in special student populations, especially those who need to learn English.

<p>Special Programs Lennox Elementary School District, 2002-03</p> <p>Special Programs information will be posted when it becomes available.</p>

Numerous special programs serve students who meet certain criteria. Assistance is provided in different ways, such as a hot meal during the school day or extra instructional time. Participation may vary from year to year depending on student enrollment.

BACK TO TOP ↑

<p>Alternative Education Lennox Elementary School District, 2002-03</p> <p>Alternative Education information is not available for this district.</p>

Numerous alternative programs meet specific student needs in addition to the regular educational program. These alternative courses of study may be mandated (as with a continuation high school) or optional (as with a magnet school). With the exception of independent study and magnets, these programs largely serve high school students.

About a quarter of California's public school students need to learn English in order to succeed in school. The percentages are highest in the early grades -- about 36% of K-3 children in 2002-03. Of the many dozens of languages in classrooms, by far the greatest number of English learners speak Spanish.

A grade-by-grade list of the languages reported in California schools is at [DataQuest](#).

15. SUPPLEMENTARY NOTES This study was performed in cooperation with the U.S. Department of Transportation, Federal Highway Administration.					
16. ABSTRACT <p>There is a significant acoustical difference between State and Federal rules governing implementation of noise abatement programs in schools impacted by freeway noise. The magnitude of that difference suggests the rules may have been based upon empirically weak grounds. This study of third and sixth grades of 15 elementary schools in the Los Angeles Unified School District indicates that California's rule is more accurate than is the Federal rule in predicting the effects of noise on reading achievement.</p> <p>Based upon this study and another independent study, a revision of the existing rule is recommended. The design criterion for traffic noise levels inside classrooms should be $L_{eq} = 58$ dB C-weighted. This criterion level is approximately 7 dB less than the current Federal standard and about 6 dB higher than the California standard.</p> <p>Because of the apparent synergistic effects of community and classroom noise levels on academic achievement, in order for the above classroom noise limit to be effective in preventing degradation of achievement from noise, efforts will be required to contain community noise levels so as not to exceed $L_1 = 65$ dBA.</p>

NOTICES

Funding for this study was provided by the Federal Highway Administration through the California Department of Transportation (I.A.A. 19-7165) and by the California Department of Health Services. Assistance of Juanita Oñate and Robert Heald in collection and analysis of the classroom data, of the Environmental Investigation Section, District 7, of Caltrans in collecting the community noise and air quality data, and of Dee Nichols for typing is acknowledged with gratitude.

The contents of this report reflect the views of the Office of Noise Control of the California Department of Health Services which is responsible for the facts and the accuracy of the data presented herein. The contents do not necessarily reflect the official views or policies of the State of California or the Federal Highway Administration. While this report contains useful information and advances the state of knowledge concerning the relationship between classroom noise and academic achievement, the report may not constitute an adequate basis for changing either the California or Federal regulations regarding acceptable noise levels in classrooms at this time. This report does not constitute a standard, specification, or regulation.

Neither the State of California nor the United States Government endorse products or manufacturers. Trade or manufacturers' names appear herein only because they are considered essential to the objective of this document.

Final Report

Effects of Noise on Academic Achievement and Classroom Behavior

Jerome S. Lukas, Russell B. DuPree, and Jack W. Swing

Introduction

Some studies have suggested that noise from external sources affects teachers' and childrens' behavior and childrens' achievement in school. For example, Crook and Langdon,¹ in a study of schools exposed to aircraft noise, found that teachers typically paused in their discourses when peak noise levels reached 80 dBA, even though voice levels were raised to compensate for the increased noise levels. With respect to academics, Bronzaft and McCarthy² found that children exposed to elevated train noise at peak levels of about 90 dBA were three to four months behind their schoolmates in quieter classrooms in reading. Cohen, et al³ reported a similar result in children exposed to aircraft noise. An unpublished preliminary study by the California Department of Health Services obtained results similar to those of Bronzaft and McCarthy and Cohen, et al. Our study suggested that reading achievement of third and sixth graders in "noisy" schools* was poorer than that of socioeconomically comparable students in "quiet" schools.

The above study raised more questions than it answered. For example, because school noise levels were unknown, we assumed that all classrooms in "noisy" schools were equally noisy, while in "quiet" schools they were equally quiet. In addition, we assumed that community noise levels were comparable. Perhaps proximity to freeways was correlated with high levels of other pollutants—lead, carbon monoxide, nitrous oxide, etc., and these may explain the difference in reading ability. Or, more simply, our results may have been due to an unique combination of schools.

In contrast to the characteristics of noise that might be expected in schools adjacent to freeways, in the other studies different levels, durations, periodicities, and sources of noise were observed. Hence, the results may not be applicable to the freeway and traffic situations found in cities.

This lack of scientific data is in part responsible for the existence of two different rules governing implementation of a noise abatement program for schools adjacent to freeways. California law states that noise abatement must occur when the noise level inside the classroom exceeds 50 dBA. In contrast, the federal program becomes operational when the noise level reaches an $L_{10} = 55$ dBA. This is equivalent to about 63 dBA⁴ under California's rule. Thus, there is a clear need to determine which of these rules is more appropriate.

The study described below was designed to examine the extent to which exposure to freeway noise affects children in school and to determine a criterion noise level for a school noise abatement program. The effects investigated were both behavioral and academic. We tentatively hypothesized that there would be correlations between external noise levels, behavioral effects,

1. A list of references and technical notes in numerical order is appended.

*"Noisy" schools were defined as schools adjacent to freeways that qualified for noise abatement work by State criteria (see below), while "quiet" schools were those nearest each "noisy" school (usually within one-half mile) but further from the freeway.

and academic achievement and that degradation of classroom behavior may explain, at least in part, reductions in academic achievement.

In addition, measures of air quality were obtained for eight of the schools under study and were selected according to (a) their proximity to the freeway, (b) their location with respect to the freeway and prevailing winds, and (c) the topography of the greater Los Angeles area. These data were used to determine roughly whether the schools studied were comparable with respect to air quality.

Method

A. Selection of Schools

The so-called "noisy" schools were selected because they were located adjacent to freeways, and because measurements by the California Department of Transportation indicated that peak noise levels in the worst classrooms exceeded 60 dBA. In addition, corrective noise abatement work was scheduled after completion of our study. It should be noted that CalTrans' noise abatement program began long before the study. Thus, we were unable to study the noisiest schools (peak levels above 80 dBA) and if we had, perhaps the effects would have spanned a greater range than those to be shown subsequently.

Two criteria were used to select the quiet schools. In general, we selected the school closest to each noisy school, but the quiet school was further from the freeway. It was assumed on the basis of the preliminary study mentioned above, that this technique would result in socioeconomically comparable "noisy" and "quiet" schools. The second criterion involved use of the teachers' estimates of parental employment to assure greater comparability. These estimates of parental employment were obtained as follows. Each year the State Department of Education requires that third and sixth grade students be administered standard tests in reading and mathematics. This test is the California Assessment Program, referred to hereafter as the CAP. The teacher fills out an information form for each child which includes a categorized question about parental occupation. The categories are: 0—Unskilled or Welfare; 1—Skilled and Semi-skilled; 2—Semi-professionals, Clerks, Sales and Technicians; 3—Executives, Professionals, and Managers. The Socioeconomic Index (S.E.I.) for a school is the average of the students tested.

This index was a rough estimate at best. Nevertheless, it was all that was available and was used for the initial selection of schools. Subsequently, more precise data were made available from several sources. These were used to develop other indicators of socioeconomic status that are shown in Table I. These indicators were calculated from the "block data" of the U.S. Census, some data provided by the Los Angeles City Planning Department, and by a private survey company. Details of the procedure for estimating the socioeconomic variables can be found in Appendix A.

Three matching quiet schools are missing in Table I. Several reasons accounted for this. One school principal refused to participate in the study because his school was not noisy. Another school was dropped when after driving through the area we found relatively few homes in an area devoted to heavy commerce which is serviced frequently by large trucks and trailers. Unpredictable delays in our schedule were caused by school holidays, and non-academic preparations for festive events such as Mothers' and Fathers' Days, Halloween, Valentine's Day, or teacher training and parent-teacher conference days. Finally, contractual and financial constraints required completion of our classroom observations in the 1978-79 school year.

S.E.I.: Socioeconomic Index. An average of teachers' rankings of parental occupation, where 0 is welfare or unskilled laborer, 1 is skilled or semi-skilled, 2 is semi-professionals, clerks, sales and technicians, and 3 is executives, professionals, and managers. To indicate variability in the Index, the top number is for 3rd grades in 1974/75, and the bottom number is for the same grades in 1975/76. A dash indicates data were not available.

Median Family Income: Estimated as described in Appendix A.

% Poverty: Percentage of families in poverty, based on average household size of 3.67 individuals - the U.S. Average. This corresponds to an income level of \$6,180, according to the U.S. Bureau of the Census for the year 1978. See Appendix A.

% Unemp.: Percentage of employable persons who are unemployed. See Appendix A.

% Black, Hispanic, and White Students: Another category, "Asian/Pacific Islander", was excluded. The percentages should add to 100%, and the difference between 100% and the sum will account for Asians/Pacific Islanders because the number of American Indians or Alaskan natives was, at most, 6 or 1.4% at school 6893. Typically, there were no or only a fraction of a percent of American Indians or Alaskan natives at these schools. Data provided by the Los Angeles Unified School District.

% N.E.S.: Non-English Speaking. The percentage of children in the 3rd and 6th grades who did not speak English with native-born fluency. In most schools these children were recent immigrants of Hispanic origin. No. 1 refers to children of "limited" ability in English, and No. 2 are non-English speaking.

No. of Students: No. in school/no. tested in 3rd 6th grades.

Comparison of the indicators in Table I suggests that our matching of schools produced roughly comparable sets of noisy and quiet schools. This assessment of comparability is correct if one accepts differences in racial composition of up to 10 percentage points or differences of more than \$1,000 in Median Family Income as not being significant. For example, in schools 9251 and 6174, the noisy school had about 10 percent more Blacks and fewer Hispanics (about 8 percentage points), and the latter school's families had \$1,000 more income yearly than did the parents of school 9251, although the unemployment rates were almost equal. Note also that despite the higher Median Family Income for school 6174, this school had a larger percentage of families in poverty than did school 9251.

Schools 7651 and 9004 were very dissimilar with respect to racial composition. These schools were initially matched on the basis of S.E.I. alone, without regard to location. In subsequent analyses, these schools were not paired.

In the aggregate, the various socioeconomic indicators suggest that the schools studied might be called minority schools because of the disproportionately large numbers of Black or Hispanic students. For purposes of comparison, the distribution of racial and ethnic groups in all of the Los Angeles Unified School District's elementary schools in the Fall of 1978 follows: American Indian or Alaskan Native, 0.5%; Black, 22.7%; Asian or Pacific Islander, 6.4%; of Hispanic origin, 46.3%; White, 24.9%. Because of the relatively high percentages of unemployed and families in poverty, as shown in Table I, our group of schools might also be called poor.

It may be concluded that the results of the study are applicable to schools of racial, ethnic, and economic comparison similar to those shown. The results may not be applicable to schools with much larger percentages of White or Asian students.

A final caution about interpretation of the Non-English-Speaking (N.E.S.) category is warranted. The decision to test or not to test a student with limited skills in English is left to the school staff. In some cases, teachers or principals may be interested in how well some or all the children are doing academically and may require tests of all, regardless of language limitations. Others may think that because some children are so poor in English, testing would be of little value, and only "Category 1" children are tested. The test score rosters contain information only about children who are tested. Thus, they reflect teacher selection of students who should be tested. The numbers should not be interpreted as reflecting relative fluency in English in the various schools. For purposes of analysis of the academic data, we have treated the children who spoke English fluently separately from those of less fluency as defined by N.E.S. Categories 1 and 2.

1. Schools and Classrooms Excluded

As a rule, we excluded schools that were part of a newly-established bussing program and classrooms that did not have full-time teachers. The behavioral data (but not achievement or noise data) from school 7214 were excluded from analysis because it was the first school studied (it was studied in the 1977 school year) and was used to test and refine our procedures. It is unfortunate that this particular school was chosen for this purpose, because it is the nearest match for school 8501.

Almost all of the principals and teachers were most cooperative, although some were suspicious initially or had reservations about the purposes of the study. Because participation was voluntary, we did not coerce teachers; rather, we used persuasion. Generally we met first with the principals, explained the program, obtained information regarding the number and locations of the third and sixth grades, teachers' names, and the number of children in the school. At this meeting we also set up a tentative schedule for our work in the school and for meeting with the teachers involved. Prior to meeting with the teachers, they were sent a brief description of the study (see Appendix B). At the meeting, this description was elaborated,

discussed, and all questions were answered. Despite these efforts, a few teachers refused to participate in the study. Some refused at the meeting, a few upon our entry into the classrooms to begin work, and some became ill on their scheduled days. If we could reschedule to accommodate the illness, we did; if not and a substitute teacher was used, the data were excluded. We also excluded data from classrooms that were almost completely out-of-control, or if most of the day(s) was spent at rehearsals, preparation for dances, preparing Valentines, Christmas decorations, etc. Occasionally the equipment malfunctioned.

Table II lists the number of classrooms and the number of days during which we obtained usable data. In some cases, usable data were obtained for a portion of the day—such as during a period devoted to mathematics. Such instances are not discriminated in the table.

It will be noted that in some classrooms we obtained data during more than three days. Typically, this occurred when a teacher of another classroom decided not to participate or became ill. Rather than wasting a day, we extended the observation period for a given classroom, if that teacher permitted. It was thought this technique would result in more accurate estimates of classroom behavior, particularly as they relate to noise levels.

2. Classrooms Combined

As will be shown subsequently, children who were not fluent in English consistently performed less well on the achievement tests than did children fluent in English. Thus, the achievement data of the two groups of children had to be analyzed separately.

In the classrooms studied, the numbers of English fluent and non-fluent children varied with the language skills of the teacher, particularly in schools with large Hispanic populations. This student distribution problem became apparent after we had observed most of the classrooms in the second school and became very clear after we had obtained the achievement test results that identified the non-English speaking students in each classroom. The reason is that the number and location of Spanish-speaking teachers does not correspond to the number of Spanish-speaking students. Thus, English-speaking students typically are taught by English-speaking teachers, whereas bilingual teachers have predominantly English-weak and non-English-speaking students.

For obvious reasons, it is invalid to perform statistical comparisons based upon samples of one or two students. Thus, we were forced to combine some data. Data from two classrooms were combined if their exposures to external noise sources were either found to be or were expected to be comparable or within 2 dB; in most cases these were adjacent classrooms. All of the classrooms, either in combination or singly, had an N of 5 or more (mean=17.2, σ =7.2). Although an N of 5 is admittedly small, the acoustics of a particular school's location or construction would not permit combination of more classrooms as being representative of a particular noise exposure. In the few cases where student numbers were less than 2 and where classroom noise levels were not comparable, the data were deleted.

B. Noise in the Communities

The fact that children are exposed to noise in their non-school environments as well as in their schools is indisputable. The problem for the study described herein is to discern the extent to which noise levels in the schools affect childrens' academic achievement independently of their non-school exposures. That achievement might be related to noise exposures in the non-school environment was suggested by Cohen, Glass and Singer⁵. They examined the reading abilities of socioeconomically comparable children attending

the same schools and residing in the same New York apartment building. They found that children living on the noisier lower floors with closer proximity to a freeway had reading levels lower than those children residing on the higher floors.

1. Method

The Noise Monitoring Survey, Class II, as developed and described by Wyle Research,⁶ was used. It is described briefly below and Appendix C describes the survey techniques in greater detail.

Students were assigned to a particular school if they lived within a distance of 1/4 to 1/2 mile of the school. Using maps of these "feeder areas" for each school, the area was subdivided into five or six locations that would estimate community noise levels considering local traffic patterns, noise sources, and the pattern of residences. These are called "spatial sampling units". Once the spatial sampling units for a given school were localized, the principal or a representative of the community was asked to provide the names, addresses, and telephone numbers of volunteers in each unit who would permit us to set up the equipment at their homes. The research group subsequently met with the volunteers, explained the study and what was expected of them, described the equipment, and arranged for an equipment set-up date. Volunteers were paid \$5.00 for each day the equipment was at their homes. Because volunteers were used, the sites were not always where we would have wished. They may have been, for example, at most a block from the ideal location. Nevertheless, the sites are believed to be representative of the sampling units.

Microphone masts were attached to the plumbing vent pipes atop the homes, and the microphones were located at the top of the mast about 6 feet above the roof. Every effort was made to prevent shielding of microphones by roof peaks and chimneys. Roofs were used to prevent shielding by adjacent buildings and to preclude vandalism.

At each sampling site, a Type 1945 Gen Rad Community Noise Level Monitor provided samples during most of the 24-hour day. A copy of a completed Community Noise Survey Data Sheet is provided as Figure 10 in Appendix C. It shows the sampling periods used throughout the day and night and the noise level indices that were recorded.

In addition to the sampling procedure with the Gen Rad 1945 at fixed sites, a Bolt Beranek and Newman Model 614 Portable Noise Monitor or a Gen Rad 1945 were used at selected "roving sites". Roving sites—two or three at each school—were used to provide better coverage of the sampling units, to corroborate data obtained at the fixed sites or, in lieu of fixed sites, if volunteers were unavailable in a particular sampling unit. Sampling durations (typically 1/2 hour) at the roving sites were necessarily shorter than those shown on the Community Noise Survey Data Sheet, but did occur within the time periods shown.

2. Community Noise Levels⁷

The community noise levels are described and discussed here rather than in the Results section because they are relevant to the comparability of the schools and are similar to socioeconomic factors.

Shown in Table III are several measures of noise levels in communities providing children to the schools. School 9251 may be compared with 6174 and 9004 as was discussed on page 3, while the four largely Hispanic schools are shown at the bottom of the table.

*L₁, L₁₀, L₉₉ and L_{NP} are averages over all sites, both fixed and roving (see Appendix C), throughout each community. The measurements occurred during Morning Rush Hours, Midday, Evening and Night.

L_{NP} for each measurement period = L_{eq} + (L₁₀ - L₉₀), and

L_{eq 24} = Logarithmic averages of levels measured during the four periods.

By and large, the differences between the "noisy" and "quiet" neighborhoods are neither consistent nor remarkably large. Indeed, some so-called quiet neighborhoods are noisier than their adjacent noisy neighborhoods (e.g., schools 9251 and 6174). Maps and observation of the areas indicate that local traffic patterns and the types of traffic are the cause. For example, although school 9251 is adjacent to a freeway, there is almost no truck traffic through its feeder area. In contrast, feeder areas for schools 6174 and 9004 are intersected by one or two major thoroughfares carrying frequent automobile and truck traffic to and from the freeway. Occasionally this traffic may bypass major intersections through residential streets. In addition, the areas are economically poor, so that many old cars in poor condition and with inadequate mufflers travel the streets. It is reasonable to expect that higher unemployment and/or poverty levels are correlated with relatively higher frequencies of decrepit automobiles; hence, there may be some correlation between the economic indices and community noise levels even in poor areas that are not adjacent to freeways.

On the average, the L_{99} appears to be the best discriminator between noisy and quiet neighborhoods; noisy areas having an average $L_{99} = 53.4$ dBA, while quiet ones average 47.5 dBA. The L_{99} may be thought of as the background, or residual, noise level obtained when the sources of noise are absent or remote from the monitoring sites.

In general, both the "noisy" and "quiet" feeder areas are shown to be relatively noisy. Only in the middle of the night at some monitoring sites in certain quiet areas did the minimum levels go down to 35 dBA or so. Compilations of noise levels at the different measurement times are shown in Appendix D; see also Figure 16, Appendix C. Because studies relating academic achievement and environmental levels are few and inconclusive, the levels shown here may be spurious. Statistical analyses described subsequently suggest the relationship between the various community noise levels and achievement.

3. Other Pollutants in School Areas^{*}

The results presented in Figure 12 of Appendix C suggest that the concentrations of lead and carbon monoxide^{*} are not related to the proximity of the school to the freeway; rather, the concentrations appear to be relatively uniform among the schools we studied in the Los Angeles Basin. It may be concluded that the children in the schools studied were exposed to similar concentrations of these air pollutants.

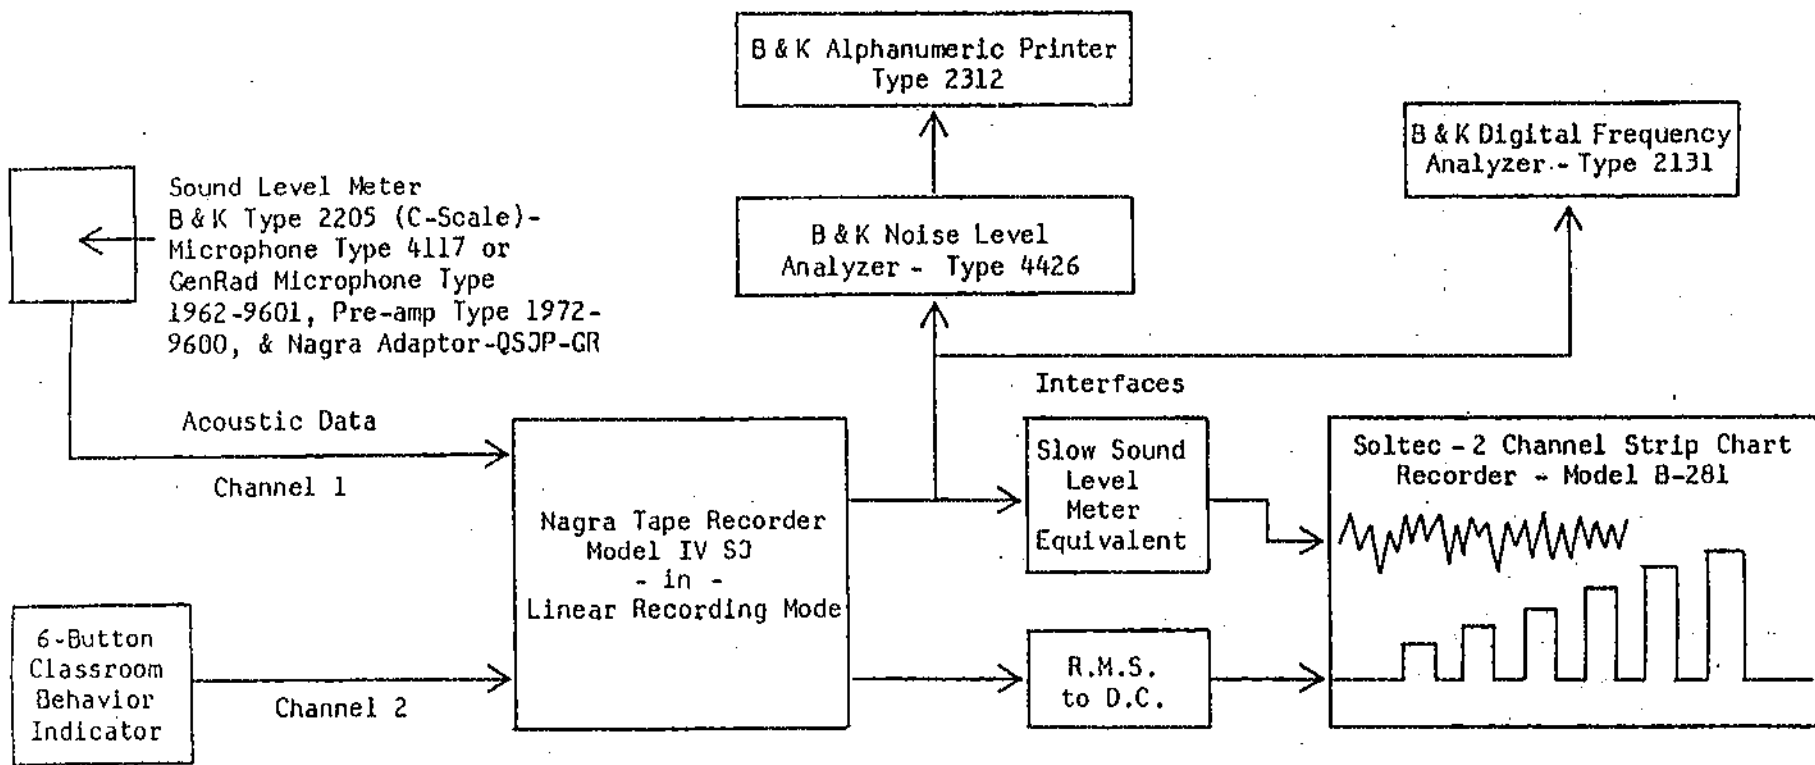

4. Classroom Measurement and Observation

While in the classrooms, two observers selectively tape-recorded two types of information: (1) the acoustic environment, and (2) certain indications of classroom behavior when the teachers were lecturing or otherwise interacting with the entire group of children. Figure 1 is a schematic diagram of the equipment used for recording and analysis.

a. Acoustical

The acoustical measurements are to be regarded as being Type 2 (ANSI S1.4-1971) for two reasons: (1) we were unable to commit, without interruption, two sound level meters as first-stage inputs (see Figure 1), which resulted in differences in the acoustical characteristics of our recordings; and (2) some initial recordings were obtained inadvertently at a tape speed (1.5 ips) that

^{*}Lead and carbon monoxide are used illustratively here. The discussion is pertinent also to other pollutants.

-10-

Figure 1

SCHEMATIC DIAGRAM OF RECORDING AND PLAYBACK EQUIPMENT

resulted in the signal to "roll-off" beyond 3,000 Hz.* The acoustical recording system was calibrated daily, and generally before beginning observation.

Noise levels were recorded under three conditions. These were:

- (1) Classroom and school areas without any children. These were obtained during the summer vacation. Ventilation (windows, doors, air conditioners, and forced air) was similar to that observed during the normal classroom periods.
- (2) Classroom noise levels with the children in position but quiet; that is, working at their seats with a minimum of talking and movement.
- (3) The observer's estimate of normal noise levels with the children present and active.

In order to calculate the Articulation Index,⁹ a sample of the teacher's voice level while reading a standard phrase (see Appendix E) at a distance of about 6 feet from the microphone was obtained. We attempted to obtain samples before and after the normal classroom hours without children present, but were hampered by faculty meetings, tardiness, and parent-teacher discussions. We were able, typically, to obtain at least one sample daily from each teacher.

b. Behavioral

In addition to the handwritten observations about the various phases of the school day and behavior therein (see Appendix B), a technique was used to record electronically pulses of varying amplitude on the magnetic tape. These pulses had a carrier frequency of 1,000 Hz, but varied in amplitude depending upon which of six buttons was pushed. Each button corresponded to a specific facet of classroom behavior, and was used to facilitate analysis of the acoustical channel of the tape. The criteria governing use of each button may be found in Appendix F. It is sufficient here to describe the six buttons only briefly:

- (1) Disregard: Used when the noise source that affected some classroom behavior was other than a motor vehicle. This button was used infrequently; discrimination of noise source was based on listening to tape recording or by annotation of the written record.
- (2) Can't Hear: Used when the observer was unable to hear what the teacher or a student was saying.
- (3) Rebuke: Used when the teacher called the class or a student to order.
- (4) Interrupt/Pause: Used when the teacher paused while instructing the students.
- (5) Distract: Used if several students looked around in the direction of a noise source.
- (6) Raise: Used if the teacher's voice was raised to compensate for an increase in noise level. (This event invariably occurred in conjunction with a "Rebuke" rather than as a response to an increase in noise level.)

Table IV shows the frequencies of the various events observed and annotated in the classrooms. It can be noted that Rebukes were the most common event, followed by Can't Hears. Because Rebukes typically were associated with an increase of the teachers' voice levels (Raise), it may be concluded that about 9 percent of Rebukes were concomitant with perceptible increases in the teachers' voice levels.

*Subsequent recordings were at a speed off 3.75 ips, which resulted in the roll-off beginning at 10 KHz.

Table IV

Disregard	Can't Hear		Rebuke	Interrupt/ Pause	Distract	Raise Voice
	Student	Teacher				
545	2380	258	6955	288	144	655

c. Comparability of Observers

After several days of practice in different classrooms, the observers worked simultaneously in a single classroom for two days* in order to determine their relative comparability. Table V shows the frequency of use of the different buttons by the two observers. McNemar's Chi-square test for correlated samples¹⁰ revealed no statistically significant differences in response frequencies between observers. However, observer H appears to have had more difficulty hearing both the students and the teacher than did observer O; and this difficulty is more apparent with respect to hearing the teacher than the students. A reason for H's apparent difficulty is that he has a significant bilateral high frequency hearing loss, as is shown in Table VI.

Detailed analysis of the strip charts (see Figure 1) indicated that the observers were more consistent than the aggregated data (Table V) initially suggested. This analysis compared only those segments of the classroom periods when observations were simultaneous.¹¹ These strip charts were synchronized, divided into 5-second periods, and a count made of the number of coincidental observations as well as the number of 5-second periods during which coincidental observations were possible. The results are shown in Table VI. Section A of the Table refers to the frequency of use of all six behavioral categories, while Sections B and C refer only to "Can't Hear" responses during periods when either the students or the teachers were doing most of the talking. For example, Section B is the sum of two periods when the children were giving answers to arithmetic problems or spelling words, and Section C is the sum of two periods when the teacher was reading a story aloud. Table VI indicates that overall the observers agreed with each other about 93% of the time. Of greater interest, however, is the indication that the observers couldn't hear the students about twice as frequently (12.6% in contrast to 6.7%) as they couldn't hear the teacher. This difference in frequencies of not hearing and hearing the teachers versus the students was statistically significant ($X^2=5.45$, $p < .025$) and is mainly due to the frequencies of not hearing rather than the frequencies of possibly hearing (the Hear-Hear cell).

*Cooperation of Ms. Nancy Ferguson is acknowledged with gratitude.

Table VI
HEARING LEVELS IN dB RE ANSI 1969

Frequency in KHZ:	Right Ear								Left Ear							
	.25	.5	1	2	3	4	6	8	.25	.5	1	2	3	4	6	8
Observer																
H	10	15	10	5	20	60	85	80	10	15	0	5	15	70	85	55
O	20	20	5	10	10	15	25	15	15	10	5	5	10	10	15	15

On the basis of the aggregate results shown in Table V it is suggested that observer H had somewhat more difficulty hearing both the teacher and students than did observer O. As shown in Table VII, that initial impression was confirmed;* however, the differences are not pronounced. It may be concluded, therefore, that the observers were responding similarly to each other and their reliability is at least 91% across all response categories.

Table VIII shows the average increases in noise level when the observers were unable to hear what the students or teacher were saying and the background noise levels (see footnote, Table VIII) prior to the Can't Hear responses. It can be seen that for both observers the changes in noise levels were usually greater when the observers were unable to hear the teacher than when they were unable to hear the students, although the background noise levels before the events were very similar. This difference, roughly 2 dB, reflects the fact that the teacher's voice level at the rear of the classroom typically was more intense than was the background noise level; hence, higher noise levels could occur before the observers were unable to hear what the teacher was saying. In contrast, the children's voices (sixth graders) probably were less intense,¹² so smaller increases in noise level caused interruption of comprehension of their speech.

The classroom in which these observations occurred overlooked a thoroughfare that handled automobile and truck traffic to and from two freeways. Thus, the background noise levels were high (see the dBC levels in Table VIII). These background noise levels were obtained when children were not present and during a brief period when, apparently, traffic was heavier than usual, as determined by listening to the tapes. Hence, the C-weighted levels without the children present were higher* than with the children, whereas the A-weighted levels were more similar but in the opposite direction; that is, A-weighted levels with children are higher than without children. The increased A-weighted levels were probably due to the voices of students and teacher (compare L_{eq} -A before with L_{eq} without children, for example).

*Observer H heard the students 84.8% of the time (81.8 + 3.0), whereas observer O heard the students 84.3% (81.8 + 2.5) of the time; and for hearing the teacher the percentages are 89.4 and 88.4, respectively.

*Traffic, particularly that containing trucks, has a spectrum showing maximum acoustical energy at frequencies below about 150 Hz. These frequencies contribute much to C-weighted noise levels but are de-emphasized in A-weighted measurements. See K.D. Kryter,¹³ pages 14, 352 and 353.

A & C are the frequency weightings used.

*

In general we attempted to measure noise levels before an event simultaneously, but were not always successful for the reason explained below, and because of differences between observers as to when to begin or stop analysis of noise levels before an event.

Sample sizes are different for the two observers because they used the button at different frequencies. For example, suppose observer H pushed the Can't Hear button twice during two contiguous 5-second periods, while observer O used it once during the second period; thus, the latter Can't Hear responses were coincidental. In this circumstance the noise levels before the Can't Hear of observer H were measured about 10 seconds before the event, while for observer O they were measured about 5 seconds before the event. In other words, although the button pushes were roughly coincidental, the noise level measurements before any event were not necessarily coincidental.

C. Academic Achievement

In April and May of the school year, third and sixth grade students in the Los Angeles Unified School District are routinely administered two standardized achievement tests. The Comprehensive Test of Basic Skills (CTBS)¹⁴ is administered by the School District, while the California Assessment Program (CAP)¹⁵ is administered by the California Department of Education. Details about these tests can be found in the manuals referenced but the tests are described briefly below.

1. Comprehensive Test of Basic Skills (CTBS)

The test battery is comprised of tests in six basic skills areas: Reading, Language, Mathematics, Reference Skills, Science, and Social Studies. The tests are designed to assess individual achievement. Only Reading and Mathematics were tested typically in our group of schools.

Reading Vocabulary and Comprehension are subtests of the Reading test and contain 40 and 45 items, respectively. Each item of the Vocabulary subtest consists of a stem phrase and four discrete words for alternatives. The student is required to choose a synonym for the key word in the stem phrase. Although the key word is part of a phrase, sentence or paragraph, the vocabulary test is a measure of the student's knowledge of the dictionary definition of the word as the context must be used to determine the key word's meaning. The items of reading comprehension assess specific skills in literal and critical comprehension; about half of the items are of each type. Forty-five items of this subtest are based upon seven selected reading passages. Some passages portray situations, feelings and emotions experienced by young people, while others provide informative material.

The Mathematics section includes sections on Computation (48 items), Concepts (25 items), and Applications (25 items). Items in addition, subtraction, multiplication and division comprise the computation section. The content of the Concepts section includes items on number systems, measurement, set theory, and geometry, and test the student's ability to convert numerical, graphic, or verbal concepts to another form. Mathematical application measures ability to select and complete problem-solving operation and include items on reasoning, algebra, measurement and set theory.

2. California Assessment Program (CAP)

The purposes of the Program are to determine the effectiveness of education in California and to provide information needed to assess the strengths and weaknesses of various educational programs in individual schools and their districts. In contrast to the CTBS, the CAP is not designed to test achievement of individual students. The CAP uses a "Matrix Sampling" technique in which each child is tested on only a small number of the questions comprising the entire test. Test scores are then aggregated over a classroom or over a grade level within a school.

The total test is comprised of 250 items; however, the test form used by any pupil contains only 25 items. Third graders took only the Reading test. Subtests of reading include Word Identification Skills, Vocabulary, Comprehension and Study-Locational Skills. The Vocabulary and Comprehension items are similar in content to those described for the CTBS. Word Identification includes items designed to measure a student's ability to identify specific words, to decode letters to their corresponding sounds, and to identify specific elements within words (e.g., root words and suffixes). Study-locational skills are those that deal with the student's ability to alphabetize and use a table of contents.

Sixth grade children were tested in Reading and Mathematics. The subtests of the sixth grade reading test are identical to those of the third grade test. The mathematics subtests are arithmetic, geometry, measurement, and probability and statistics. Each subtest includes items to assess skills in computation or knowledge, comprehension, and application of mathematical concepts.

D. Data Analysis

Because of the variability in socioeconomic composition and in noise levels in the classrooms and communities of both noisy and quiet schools, a multiple regression analysis was conducted.¹⁶

While planning the study, we hoped to conduct our analysis between classrooms; that is, in a given school a comparison of noisy and quiet classrooms was planned. However, this plan became infeasible after we observed the daily operations of the schools.

Our observations and discussions with teachers and principals indicated that achievement scores of the various classrooms at each grade level within a school should be averaged for the following reasons:

- (1) Many children moved from their homerooms to another room for reading, mathematics, or another subject depending upon skills and interests of the students and teachers, or if a teacher was absent and a substitute was not available. Thus, in many cases noise exposures may have varied with subject matter.
- (2) In some schools students of varying academic skills were not randomly distributed between classrooms. As an example, see the discussion in Section A.2. (Classrooms Combined) regarding the classroom assignments of non-English-speaking children. Thus, some variability in achievement was associated with classroom assignment.
- (3) Achievement scores between classrooms within a school were not consistently statistically different (see below).
- (4) Socioeconomic and community noise variables were available only on a community-wide basis; that is, they were not specific to a classroom or to a student within a classroom, whereas the CTBS scores were specific to each child. Noise levels within the schools were appropriate for each classroom. It appeared preferable, therefore, to use data based upon relatively uniform units of observation: at grade level within a school.

Results

A. Academic Achievement

At the outset, it should be noted that the achievement data of the English-speaking (E.S.) and non-English-speaking (N.E.S.) children are treated separately. This was necessary because, as expected, N.E.S. children do less well academically than do children who are fluent in English, particularly in reading. Differences between English and non-English-speaking children are less apparent for mathematics. Table IX shows the range of Grade Equivalents in Reading and Mathematics for all of the classrooms and schools studied. Grade Equivalents are used because they are more meaningful to the reader than are Expanded Standard Scores.¹⁷

Also shown in Table IX are the F ratios between mean achievement scores for the classrooms in each school and the corresponding degrees of freedom (df). In the df column the number to the left of the comma is pertinent to the number of classrooms, while the number to the right refers to the number of students in the different classrooms. In some schools the number of N.E.S. students was so small as to preclude calculation of meaningful F ratios; nevertheless, the mean achievement for those students is shown. In other schools (e.g., school, 6802, Grade 3), the number of N.E.S. students in each classroom

* Percentiles relative to all other 3rd or 6th grades in schools throughout the State of California. They are based upon the mean percent correct.

** () For comparison these are the percentiles for the CTBS Test (Table XII) relative to samples of students completing 3rd and 6th grades throughout the United States.

*** The socioeconomic mix in School 9004 was similar to that of 9251. Thus, they may be compared.

was admittedly small, but the analysis of variance was completed simply to show the trend.

Comparison of the grade equivalents for E.S. and N.E.S. will show that the N.E.S. students were almost uniformly behind their English-speaking schoolmates. The exception was among the 6th graders in school 7941, where their reading achievement scores were equivalent. But note that among the N.E.S. students within each school, achievement in Mathematics, which is somewhat less language dependent, is greater than that in reading. A similar trend is found among the English-fluent students, but is less consistent and less pronounced than in the case of N.E.S. children.

Table IX shows also the schools in which statistically significant differences in achievement scores between classrooms were attained. As shown in Table X, the distribution of these significant differences suggests that the E.S. students are more likely to show differences in achievement between classrooms than are the N.E.S. students. Although the distributions for the sixth grade students are not significant statistically, they exhibit the trend shown by third grades. However, these distributions may simply reflect the lack of power of the Analysis of Variance test when samples are small. Hence, it is reasonable to be cautious when interpreting the achievement data for the English-weak students.

1. An Overview of Measures of Achievement

Table XI shows the average achievement in Reading and Mathematics in the noisy and quiet schools that are similar with respect to the socioeconomic variables. Four noisy schools which had Hispanic populations of 92 percent or more are not included because comparable quiet schools were not available. Data from these four schools are included subsequently in the multiple regression equations.

With respect to Table XII, it is apparent that both third and sixth grade children in noisy schools generally did less well academically in both Reading and Mathematics than did their counterparts in quieter schools. On average, third graders in noisy schools were about 0.4 year behind in Reading, while the sixth graders were about 0.7 year behind. In Mathematics, third graders in noisy schools were about 0.2 year behind, while the sixth graders in noisy schools were about 0.2 year ahead. This reversal was due to the superior performance in Mathematics by both sixth grade classrooms in a single school, no. 6802. Why these children did so well is unknown, because of the small number of classrooms in this school and in this subset of the Mathematics data, the results should not be interpreted too broadly.

On the average, this group of schools is not "up to par". After approximately three years in school the third graders should have grade equivalents of nearly 4.0, while the sixth graders should be at or near 7.0.

It is of interest to note that the children in most of the schools had slightly better scores in Mathematics than in Reading. This result may be partially due to the test and normative group used as is suggested by the scores obtained on the CAP test shown in Table XIII. These data are in the form of percent correct, and in this form are difficult to interpret because of a lack of normative data. Therefore, shown at the bottom of Table XIII are percentile ranks corresponding to the mean percent correct. It is expected that an average number of correct responses for a particular grade level would correspond to the 50th percentile. With respect to better performance in Mathematics than in Reading, it will be seen that when only California schools are compared sixth grade children in noisy schools were 2 percentile points higher in Mathematics, while in quiet schools equivalent percentiles in Reading and Mathematics were obtained. If comparison is based upon a sample of the students throughout the U.S. (in parenthesis), it will be seen that in the quiet sixth grades performance in Mathematics was poorer than it was in Reading.

6	-.478	-.420	-.337	-.544	-.239	-.327	-.142	-.051

* Limitations of the equipment and time precluded C-weighted measurements. Thus, the neighborhood noise levels are A-weighted.

Aside from certain small discrepancies, the trend of the data for quiet versus noisy schools is consistent for both tests; children in quiet schools attained higher achievement scores than did children in noisy schools. It should be noted, however, that some of our so-called quiet schools were, unexpectedly, not quiet, and their noise exposures may account for the poor achievement shown. For example, school 9004 was located on a thoroughfare that fed traffic, including many trucks, to and from a nearby freeway. This school was also under a segment of the approach pattern to Los Angeles International Airport. The average noise level outdoors at this school was 60 dBA (L_{eq} , measured outdoors for 8 hours). In comparison, at three of the so-called noisy schools the noise levels were about 62 dBA, and at the next quieter school (6893) noise levels outdoors were 58 dBA. Individual classroom noise levels depended upon the orientation of the classroom to the predominant noise source in the area. Thus, the distinction between "noisy" and "quiet" schools was found to be based upon small differences in noise levels; A multiple correlation paradigm was selected for statistical analysis because it takes these small differences into account.

B. Noise Levels in Classrooms

The noise levels, their predominant sources, and the articulation indices observed, or estimated, in the classrooms are shown in Tables XIV and XV. It is apparent that there was a broad range of noise levels in the various classrooms of both noisy and quiet schools. On the average the designated noisy schools were noisier than were the quiet schools, but in comparing individual classrooms some notable exceptions may be found. For example, in the third grade classroom 47 of school 7651 (Table XIV) the C-weighted L_1 level due to an air-conditioner was 63 dB, while in 5 classrooms exposed to local traffic in school 9004, L_1 's were 64 dB. In classroom 17 of school 9004 which was exposed to truck traffic on an adjacent street, the A-weighted L_1 was 5 dB higher than was a comparable classroom in 7651 which was near a freeway. The effect of local truck traffic on classroom noise levels in these two schools is even more pronounced in the case of certain sixth grade classrooms (Table XV). In school 9004, the 4 sixth grade classrooms are arranged in an L shape, in which classrooms 4 and 5 are the base of the L and parallel to the street; the narrow, windowless side of classroom 4 is facing oncoming traffic on the near-side of the street. Classrooms 6 and 7 make up the side of the L and are partially shielded from outgoing traffic by an adjacent building. The center of the window side of classroom 7 is about 100 feet from the centerline of the nearest traffic lane. The observed noise levels in the four classrooms were consistent with the configuration of the rooms but, more importantly, in two classrooms noise levels were found to be much higher than those observed in its matching noisy school.

Other, similar comparisons of schools and classrooms can be drawn. The point is that the so-called quiet schools were in many instances noisier than were the so-called noisy schools. Our analysis required that the noise levels in classrooms be accounted for regardless of whether the source of the noise was a freeway, local traffic, or air-conditioning.

C. Correlations Between Noise Levels and Achievement

Table XVI shows the correlation coefficients between noise levels as measured by the several descriptors in question averaged over the classrooms in each school and the achievement scores averaged over the same classrooms using the CTBS test results. The CTBS, rather than the CAP, is emphasized because performance on the CTBS can be evaluated with respect to some expected criterion. For example, children completing the third grade should attain a grade equivalent of about 4.0. Thus, grade equivalents provide a norm against which the effects of noise can be evaluated.

The magnitudes* of the coefficients shown in Table XVI suggest that noise had a more systematic effect upon sixth graders than upon third graders and that noise appears to have more predictable effects upon the skills involved in Reading than those in Mathematics.

A likely reason for the difference between Reading and Mathematics is that acquiring skills in reading depends more upon verbal interactions between teacher and student and the need for the teacher to correct student errors, for example in pronunciation. Such interactions are known to be affected by noise. Performance in Mathematics, in contrast, is more dependent upon solitary student practice and the student learning to perceive and understand abstract relationships; such tasks are less likely to be affected by noise. This hypothesis is supported by the relationships between scores on the Reading and Mathematics tests and the Articulation Index (AI), which is a measure of how well one is likely to understand speech spoken at a certain intensity given some intensity and spectrum of noise in the background. In general, the correlations between Reading scores and the AI are small but positive (see Appendix G for details), whereas they are smaller (nearly zero) but negative with respect to Mathematics. In other words, as the AI improves Reading performance also tends to improve, but for Mathematics there is only a slight or negative relationship.

The reasons for the generally smaller coefficients for third graders than for sixth graders are unclear. In part, they may be due to a statistical artifact. The range of achievement scores for third graders was much smaller (for Reading, from 2.2 to 4.1) as compared to a range from 4.3 to 8.4 for sixth graders. It is also possible that the data reflect to some degree the cumulative interaction of noise and achievement.* Deficits in achievement due to noise in the first several years of school may become progressively greater as a child continues through school, so that in grade six noise may be more disruptive because it is acting upon a weaker scholastic base.

Similarly, Bronzaft reported (during the Acoustical Society of America's meeting in Los Angeles Ca, on 20 November 1980) that the effects of elevated train noise were less pronounced on the reading scores of third graders than on those of sixth graders. She attributed the difference to sixth graders obtaining less individual attention from the teachers than did third graders. We observed little difference in the amount of individual instruction given third and sixth graders.

1. Preferred Classroom Noise Descriptor and Predicted Achievement

One question posed in the Introduction is which of several descriptors of noise is the best predictor of the relationship between noise and academic achievement. The subsequent statistical question is which noise descriptor is correlated most highly with academic achievement. Implicitly, State law says L_1 * is, whereas the FHWA's Guidelines say an L_{10} is correlated more highly with achievement.

Furthermore, the State suggests that a significant detrimental effect on the educational process begins when a noise level of 50 dBA is obtained, while the Federal Guidelines suggest such an effect begins at 63 dBA.

If we confine attention to Reading achievement in Table XVI, it is quite clear that for both third and sixth graders the C-weighted descriptors of noise level are more highly correlated with Reading achievement than are the A-weighted levels. Furthermore, the coefficients associated with the L_1 descriptors are higher than with the

*We are considering here only the absolute magnitude of the coefficients, regardless of whether they are statistically significant.

*In this regard it is important to observe that on the average approximately 65 percent of the students attend these schools since Kindergarten.

*California State Law specifies the noise level in terms of a single event maximum or peak level. In usage, however, the law is less restrictive. For our purposes, the L_1 level appears appropriate.

L_{10} descriptor; the L_{eq} descriptor is nearly equivalent to or higher than that of the L_1 . These results suggest that L_1 or L_{eq} C-weighted should be used in the multiple regression equation to predict achievement. Several noise descriptors could be used in the calculations, but because of the high intercorrelations between the descriptors (Appendix G), and the need to obtain a single descriptor and level to be used as a criterion level for purposes of noise abatement, only a single descriptor is used in the equation. It is the L_{eq} C-weighted.

2. Preferred Community Noise Descriptor and Predicted Achievement

As shown in Table XVII, noise levels in the neighborhoods appear to be related to childrens' achievement. Noise levels in the communities appear to have a greater effect upon achievement in reading than in mathematics, but the trend is somewhat less consistent than was the case for classroom noise levels. For example, with respect to the reading achievement of third graders, the L_{10} coefficient is greater than is that of the L_1 or L_{eq} . However, in both grades the L_{99} levels are most highly correlated with reading achievement, while for mathematics the L_{99} levels are less highly correlated than are some of the other descriptors. These variations may be statistical artifacts due to the small number of schools.

For purposes of the multiple regression equation, the L_1 descriptor was used because it had the smallest range of coefficients (from -.327 to -.420), and is perhaps the better estimate of the actual correlation between community noise levels and achievement in both reading and mathematics. Furthermore, the noise events associated with L_1 are more likely than are L_{99} events to intrude into the home.

3. Socioeconomic Variables

Table XVIII shows the correlations between certain socioeconomic variables, achievement, and selected noise measures. These data indicate that as the percentage of families in poverty increases, achievement in reading and mathematics decreases. A similar relationship exists with respect to the percentage of Blacks in the community. In contrast, as the Hispanic population increases there appears to be a trend for higher achievement in mathematics, but no such trend is apparent with respect to reading achievement. This may be due to the fact that, on the average, as the Hispanic population increases there is a corresponding decrease in the percentage of that population which is fluent in English.

As the White population increases, there is higher achievement in both reading and mathematics. The percentages of Blacks and Whites were included in the multiple regression equation because achievement appears to be related to these ratios and because the intercorrelation of these percentages is relatively small (≈ -0.4) as compared to the intercorrelation of the percentages of Blacks and Hispanics ($= -0.9$) (see Appendix G).

Several trends in the data shown on the right side of Table XVIII are of interest. It is apparent that as noise levels in the community increase, median family incomes decrease; or poor people live in noisier neighborhoods. Whites live in quieter communities and attend quieter schools than do Hispanics. Blacks appear to go to quieter schools than do Hispanics, but the Blacks live in somewhat noisier neighborhoods.

D. Predicting Achievement from the Selected Noise and Socioeconomic Variables

Figure 2 illustrates the predicted¹⁸ relationship between Reading grade equivalent in third graders as a function of noise level (in units of L_{eq} C-weighted) averaged over the classrooms in each school, with different average noise levels (in units of L_1 A-weighted) in the 15 communities. Different proportions of Black and White students may be assumed;

Table XVIII

COEFFICIENTS OF CORRELATION BETWEEN SOCIOECONOMIC VARIABLES, ACHIEVEMENT IN READING AND MATHEMATICS, AND INTERCORRELATIONS BETWEEN SELECTED VARIABLES

	Grade Level	Median Family Income	% Families In Poverty	% Black	% Hispanic	% White	Variable	Median Family Income	% Black	% Hispanic	% White
READING	3	.217	-.325	-.342	.021	.697	Classroom* Leq C	.103	-.243	.385	-.257
MATHEMATICS	3	.212	-.311	-.699	.446	.645	Community L ₁ A	-.438	.211	-.041	-.428
							% Poverty	-.343	-.028	.267	-.524
READING	6	.360	-.545	-.439	.104	.676	Classroom* Leq C	.035	-.201	.291	-.218
MATHEMATICS	6	.328	-.437	-.667	.408	.493	Community L ₁ A	-.573	.178	-.033	-.408
							% Poverty	-.416	.038	.153	-.493

*These coefficients were calculated from noise levels measured in each classroom, but the other variables were community-wide aggregates.

Figure 2

RELATIONSHIP BETWEEN READING ACHIEVEMENT OF THIRD GRADERS AND CLASSROOM NOISE LEVELS GIVEN DIFFERENT NOISE LEVELS IN COMMUNITIES
The Population is Assumed to be 23 Percent Black and 24 Percent White

The upper curves illustrate the estimated relationship between reading achievement and noise levels in the classroom and the community assuming that the racial composition of the schools is 23% Black and 24% White, 46% Hispanic and 7% other. It shows that at any given classroom noise level as the noise level in the community increases, reading achievement decreases. Conversely, at a constant noise level in the community, achievement in reading decreases directly with increasing noise level in the classroom. The lowest curve shows the results for this sample of schools in which the racial and noise level parameters differ from those assumed for the upper curves. Because the curves are parallel, decreased noise levels in the communities should result in a shift upward of the lowermost curve.

Figure 3

RELATIONSHIP BETWEEN READING ACHIEVEMENT OF SIXTH GRADERS AND CLASSROOM NOISE LEVELS GIVEN DIFFERENT NOISE LEVELS IN COMMUNITIES
The Population is Assumed to be 23 Percent Black and 24 Percent White

School District: 23 percent Black and 24 percent White.

Most remarkable about these data is the apparent trade-off between noise levels in the community and those in the classroom. In other words, if the community is quiet, more noise in the classroom can be tolerated without appreciable effect upon reading. For these third graders it appears that a 10 dB increase in community noise level is equivalent to about a 20 dB increase in classroom noise level. The magnitude of this trade-off is due to the low correlations between reading achievement and noise levels in the classrooms and communities, which in turn may be due to the limited range (1.9 G.E. units) of achievement. Indeed, the multiple correlation does not attain statistical significance.

In Figure 2, the bottom, dashed line represents the results for this sample of schools given its average racial composition and the average community noise level. Clearly, on average this group of students was not achieving at grade level; that is, near or at 4.0. Rather, average achievement was 2.9 units in reading. The highest achievement was attained at a single school with a grade equivalent of 4.1, the lowest was 2.2.

Because the multiple correlation was not statistically significant, and because of suggested possible cumulative effects of an early educational deficit, it appears unwise to belabor further the third graders' data.

As is illustrated in Figure 3, the effects of noise level in classrooms were more pronounced with sixth graders than was the case with third graders. Here a 10 dB increase in classroom noise level resulted in a decrease of about 1.5 grade equivalent units, or about .15 units per dB. Community noise levels have less effect; a 0.9 grade unit decrease for a 10 dB increase in noise level, or about 0.1 grade unit per dB. It is worthwhile to note that the degradation in reading with increases in community noise level is consistent with the findings of Cohen, Glass and Singer.⁵

E. Results with Non-English-Fluent Children

The Correlations between achievement in reading and mathematics and classroom noise levels for the non-English-speaking and English-weak students are invariably low; details may be found in Tables G-3 and G-4. It is likely that this is a result of the students' general inability to read and understand the English language, as is reflected in their generally low and narrow range of achievement scores (see Table IX). It is reasonable, therefore, not to discuss these data further.

F. Implications Regarding Classroom Noise Levels

Because of the trade-off between classroom and community noise levels, it is clear that the proscribed level for classrooms depends upon the noise level obtained or that which may be proscribed for the communities. Our sample of communities had average L_1 levels of 69.3 dBA or an $L_{eq} = 60$ dBA. The effects of those levels on the childrens' achievement are shown in the lowermost curve of Figure 3. Again, as in Figure 2, the socioeconomic variables are those found in our sample. Use of the lowermost curve to establish a criterion classroom noise level appears unwarranted because the percentage of White children is low while the percentage of Black (and Hispanic, as well) children is high as compared to their distribution throughout the school district. Consequently, at this time it seems advisable to use one of the upper three curves to establish the criterion level. We have selected an $L_1 = 65$ dBA as a criterion community noise level for several reasons: 1. It is equivalent approximately to an $L_{dn} = 60$ dBA, which is the estimated exposure of about 54 percent of the urban population of the U.S.;¹⁹ 2. An L_{dn} of 60 dBA is near the upper limit for single family residential areas recommended in California;²⁰ 3. It encompasses the FHWA criterion for highway noise impacting upon a sensitive outdoor space of $L_{dn} = 60$ dBA;²¹ and 4. The reduction of noise levels in urban communities to more satisfactory levels is likely to be a slow process.

Assuming that the average achievement of children completing the sixth grade should be about 7.0 grade equivalent units, Figure 3 indicates that the L_{eq} C-weighted in the classroom should not exceed 59 dB. This level in units of L_{eq} A-weighted is about 46 dB, and equivalent to an L_{10} = 48 dBA. It is interesting to note that this latter level is only about 2 dB higher than that recommended (L_{10} = 46 dBA) in the National Cooperative Highway Research Program Report No. 117, which was based primarily upon degradation of the Articulation Index by noise. This document apparently was used to establish the federal noise abatement criterion level.

G. Classroom Behavior

Tables XIX and XX present average noise levels in units of L_{eq} C-weighted under three classroom conditions: without children, with quiet children, and with typical activities ongoing. Children were considered to be quiet when they were working individually in their workbooks, for example, and there was no verbal interaction between students and teacher, although some students may have been talking together. Typical activities were those in which the children and teachers were interacting, some children may have been moving around, and some were perhaps shuffling papers, pencils, feet, etc. The tables also include the changes in noise levels relative to the typical level that precluded hearing what the teachers and students were saying, the Articulation Index given the teachers' voice levels, and an estimate of the relative incidence per unit of time that the observers were unable to hear the teachers and students. This latter number is a rough estimate because of the problem of determining, on the basis of the daily classroom log, the exact number of minutes or number of opportunities during some activity when the teacher and students were attempting to communicate verbally. For example, during a session devoted to spelling, the teacher may call out a word to be spelled, she or he then looks around the room for hands or otherwise selects a student to respond, calls a name, repeats the word, at which time and after some delay the student attempts to spell it. Although the time used by the teacher to speak the word, the student's name, and the student's response may be brief, the intervals between these events are of variable and of unspecified duration. Furthermore, preparation times for activities such as putting word lists away before a spelling test or finding a reading book were of highly variable durations and appeared to depend upon the demeanor of the students. Despite the limited value of these results, they are presented herein to provide an approximation of the inability to hear speech in the classrooms studied. When this normalized Can't Hear rate was used as the dependent variable and the other variables (excluding can't hear teacher because of the limited sample) were used as independent variables in a multiple regression equation, the multiple correlation coefficients were low (≈ 0.20 for both third and sixth grade classrooms) and statistically insignificant. The intercorrelation matrix for both grade levels are provided in Appendix H.

The data presented in the two tables discussed above are combined in Table XXI in order to show the average values of the variables aggregated on the basis of whether or not the classroom noise levels without children present exceeded 58 dBC (see Section F. above). Also included are the average voice levels (in L_{eq} -C) of the teachers. In Table XXI it may be seen that in the classrooms with high background noise levels (greater than 58 dBC) the contribution of the children to the noise level is small compared to classrooms in which background levels are at or less than 58 dBC. Specifically, in the noisy classrooms background noise levels prevailed so that when the children were present but quiet noise increased only 1.5 dB (an average over the third and sixth grades), but if typical activities were ongoing noise levels increased by about 3.5 dB. In contrast, in the quieter classrooms the presence of children (due to paper shuffling, some whispering, etc.) added about 8.5 dB to the levels, and typical activity added about 12.5 dB to the background levels. But the fact that similar typical levels were found in both groups of schools suggests that children generate limited amounts of noise. Thus, in schools in noisy areas outside sources of noise prevail, whereas in quiet schools noise generated by the children is

SAL00018

predominant. Because our typical noise levels include the voices of teachers and children and because at times the child speaking was very close to the microphone, the noise levels when the children were quiet is the better basis for estimating how noise affects classroom communication. Classroom observations indicated that when noise levels due to the children's activities became too high (i.e., at or near the typical levels) the teacher called the class to order and paused until the disrupting activities stopped.

Table XXI indicates that in this group of noisy schools the teachers' voice levels were on the average about 1 dB over the Quiet Children condition; hence, the change in level necessary to obscure the teachers' voices was less than was the case in quiet schools where the teachers' voices were about 3 dB above the Quiet Children condition. It must be remembered that the teachers' voice levels were measured at a distance of six feet, but in the classroom the recordings were obtained when the teacher was at a greater distance. Thus, teachers' voice levels as recorded during the classroom observations probably were about 4 dB less intense (as estimated from Ref. 12) than those shown in the table. In these noisy schools the teachers' voice levels at the back of the room were very near the background noise levels without children present. In these quiet schools, in contrast, at the rear of the class the teachers' voice levels were about 7 dB above the levels without children present, and near the levels observed when the children were quiet.

Because estimates of childrens' voice levels are unavailable* a similar analysis of their probable intensities at the teacher's ear cannot be made. However, the intensity changes associated with an inability to hear the children are small and typically negative, indicating that the levels during the Can't Hear event were indistinguishable from or less than the typical level. Furthermore, it is reasonable to hypothesize that in these noisy schools the childrens' voice levels were frequently at or below the levels observed when the children were absent, and that the teacher may have had difficulty hearing ~~was~~ ^{what} was being said. We observed instances, particularly in noisy classrooms, in which children mispronounced or misspelled a word without correction by the teacher. Presumably, the teacher did not hear the error, and upon subsequent questioning the teacher admitted that she had not heard.

As is to be expected, the articulation indices in this group of noisy classrooms is lower than in the quiet classrooms. In addition, the earlier finding that children in quiet classrooms do better academically than children in noisy classrooms is seen again.

Teachers have observed that as a result of noise children are less well behaved and require more direct control than do children in quieter classrooms. It was thought that a simple test of this observation might be to count the number of rebukes of the children and the number of times a class is called to order to discern if such numbers are related to the classroom noise levels. Hence, Table XXII presents the number of rebukes as an average over classrooms and the average noise levels extant shortly before those rebukes occurred. Noise levels before the event were recorded because of the possibility that a noise threshold must be reached before the teacher calls the class or individual children to order.

It will be seen that there appears to be no relationship between the number of rebukes and the noise levels occurring just before a rebuke. Furthermore, there are no differences in the number of rebukes observed in these groups of noisy and quiet classrooms. These limited data suggest that calls for order were precipitated by levels of about 69 dBC.

In order to assure ourselves that this result was not due to the way the classrooms were divided, we calculated the intercorrelation matrix of the three variables shown in Table XXII and the relative frequency of rebukes based upon total observation time in each

*Pearsons et al.¹² measured voice levels of children under age 13 in an anechoic chamber. Whether childrens' voices in school have comparable intensities is unclear. Our observations indicate they are less intense. In fact, some children appeared to be whispering at times.

classroom. Correlation coefficients between the noise levels and both rebuke frequency measures were on the order of 0.05.

Discussion

That a negative relationship exists between classroom noise levels and reading achievement has been demonstrated by this study, Bronzaft and McCarthy,² and Cohen, et al.^{3,5} A similar relationship between community noise levels and reading achievement has been shown herein as well as by Cohen, et al.⁵ and Green, et al.²² In these studies the sources of noise were aircraft, freeways and local thoroughfares, and elevated trains. Retrospectively, it is perhaps not surprising that both community and classroom noise levels are correlated with achievement levels if we consider how noise from such sources is propagated throughout the community. Indeed, as was shown in Appendix G, there was a high correlation ($r=0.65$) between classroom noise levels in units of L_{eq}^C and background noise levels (L_{99}). Furthermore, the classroom C-weighted levels were more highly correlated with community levels than were the classroom A-weighted levels, which probably reflects the fact that low frequencies propagate more widely and with less attenuation than do the higher frequencies.

What this study and most of the others fail to demonstrate (although some investigators did not try) is the immediate effect of noise on classroom behavior or operations. The exceptional study was that of Crook and Langdon,¹ which showed that as noise from aircraft flyovers intensified there was an increasing incidence of (1) an inability to hear what teachers were saying, (2) pauses by teachers to permit the noise to cease, and (3) increases in the teachers' voice levels in compensation for the noise. In the noisy classrooms of this study, noise events such as passbys of trucks, motorcycles, or noisy automobiles were difficult to measure from the tape recordings because of the generally high background noise levels due to heavy traffic and the ongoing discussions between students and teachers. Thus, an event, although audible, was acoustically indistinguishable. Despite this inability to demonstrate certain behavioral effects of noise, the fact that independent studies with a variety of noise sources show less achievement in noisy schools and communities indicates that noise hampers the educational process in some way. Cohen and Weinstein²³ have suggested several possibilities. Moreover, it appears that early academic deficits due to noise become progressively worse. Because of this progressive deficit and because children are exposed to community noise well before their exposures in classrooms, it appears that abatement of community noise should be emphasized more than abatement of classroom noise. Of course, if community noise is abated classroom noise will be also.

Abatement of classroom noise is a relatively simple problem technically* and has been shown to be of some benefit to the students academically.^{3,24} The question of importance for this study was, "What should the criterion noise level be?"

In terms of behavioral effects the results are equivocal, but in terms of academic achievement the results are more clear, notwithstanding the fact that children do contribute to background noise levels. As was pointed out with respect to Table XXI, when the children in noisy schools were relatively quiet the predominant source of noise was traffic. Here the children when quiet added only 1.5 dB to the background traffic level, which might be accounted for by the variance of traffic noise rather than the presence of the children. On the other hand, in the quiet schools the noise level with children quiet was about 3.0 dB quieter than were the noisy schools without children present. If we assume that when children are quiet they produce an L_{eq} of 63 dB C-weighted,* then logarithmic addition of the noise levels observed in the noisy classrooms from traffic alone (64.5 dB as an average over the third and sixth grades) to another random

*Reducing community noise levels is technically and politically difficult because it appears that a major requirement will be to reduce noise levels at their sources, and organized opposition to such attempts has been amply demonstrated during recent history.

*This level is consistent with that reported by Pearsons, et al.¹² Comparison of A- and C-weighted L_{eq} s when only trucks and local traffic were the noise sources indicates that $L_{eq}^C - 13 = L_{eq}^A$ -weighted.

noise of 63 dB (children quiet) will result in a total noise level of about 66.5 dB. As may be seen in Table XXI, this is very close to the noise levels observed in the noisy classrooms with children present but quiet. In other words, noise levels from outside sources appear to have a major influence on classroom noise levels when the children are present and quiet. This analysis suggests that noise levels resulting from the presence of quiet children should not be taken into account in developing a criterion noise level for an abatement program.

Furthermore, teachers have the responsibility for controlling noise levels in their classrooms in order to assure that adequate communication is possible, but they have no control over external sources of noise. These external sources may influence their vocal efforts.¹² But, despite these efforts the Articulation Indices calculated in this group of schools show that in noisy classrooms the average (over third and sixth grades) Articulation Index was .77, whereas it was .95 in the quiet classrooms. Although the first number is some 19% less than is the second, according to the usual interpretation of these numbers speech communication should be adequate if the teacher is talking. Our observations indicated that children do not speak as loudly as do the teachers. If we consider that education depends upon interactions between students and teacher, then given the apparently lower voice levels of the students and, at times, their less than ideal distance from the teacher, it can be hypothesized safely that high background noise levels from external sources are a greater detriment to the ability of the teacher to hear the student than is the converse. Indeed, the observers recorded an inability to hear the students about 9 times as frequently as their inability to hear the teacher when all of the data were combined (Table IV), and about twice as frequently when the observation periods of teacher versus students were controlled (Table V). Finally, the changes in level recorded when the observers were unable to hear the children were near or below typical noise levels (see Table XXI), which suggests that discrimination of a single voice from a noise milieu is a difficult task for the teacher and should be accounted for in establishing a criterion level for noise abatement. It is thought that using the reading achievement results, which appear most sensitive to noise, provides conservative but indirect assurance of accounting for the teachers' difficulty.

Conclusion

A recommended design criterion for traffic noise levels inside classrooms ($L_{eq} = 58$ dB C-weighted)* is advanced on the basis of two independent studies: The one reported herein and the National Cooperative Highway Research Program Report No. 117.^{25, 26} This recommendation should be accepted as the basis for revision of current standards pending the availability of additional information.

Because of the apparent synergistic effects of community and classroom noise levels on academic achievement, in order for the above classroom noise limit to be effective in preventing degradation of academic achievement from noise, efforts will be required to contain community noise levels so as not to exceed $L_1 = 65$ dBA.

*This level is equivalent, approximately, to an $L_{10} = 48$ dBA, which is 7 dB less than the current Federal standard ($L_{10} = 55$ dBA), but about 6 dBA higher than the California standard ($L_1 = 50$ dBA = $L_{10} = 42$ dBA). Use of the C-weighting is recommended because C-weighted sound level measurements are more sensitive to the lower sound frequencies found in traffic noise and are generally more highly correlated with achievement in reading.

Technique for Estimating Several Socioeconomic Indicators Applicable to the 1978/79 School Year for Selected Schools

Study of census data showed that neighborhoods providing children to a certain school are encompassed by several different census tracts and incorporate only small parts, or "blocks", of the much larger census tracts and in most cases the socioeconomic data (% poverty, median family income, etc.) for each tract were different. Thus, the problem arose of developing a technique for using existing census data - that are applicable to or described in terms of large areas (tracts) - to the specific, smaller neighborhoods feeding children to the specific schools studied.

Technique:

The Los Angeles City Planning Department indicated that the neighborhoods of interest had not had significant changes in the number of dwelling units during the preceding ten years or so. Thus, using the 1970 U.S. Census as a data base, the procedure described below was followed:

1. From maps showing the areas feeding children to our schools and from Census Tract maps - that show Census Block numbers within each tract, we determined the specific Census Blocks that provided children to each of our schools.
2. From the "Census Block Within Tract" data we obtained the number of housing units in each block that contributed children to each school's population.
3. Then we calculated the fractional contribution of a particular block (or blocks) of a tract to a school's population by using the total number of housing units in a tract as the denominator and the number of housing units obtained in Step 2 as the numerator. This fraction was calculated to 3 decimal places.
4. Fractional contributions (Step 3) were calculated for each census tract contributing children to a particular school.
5. The fractional contributions of each tract contributing children to a particular school were multiplied by the median family income, percent in poverty, and percent unemployed for each corresponding tract, and the products summed to arrive at the socioeconomic indicators shown in Table I.

Mr. Fred Ige of the Los Angeles City Planning Department concurred with the technique, and Mr. Thomas Smuczynski of the Los Angeles City Planning Department provided 1977 estimates of median family income, percent in poverty, and percent unemployed. These 1977 estimates, by census tracts, were obtained from a study conducted by the Planning Department and were based on a two percent sample of households in the City of Los Angeles.

In nine cases the tracts were not in the City of Los Angeles. The 1977 estimates for these tracts were obtained from Urban Decision Systems, Inc., at the suggestion of the Los Angeles County Planning Department.

Jane Rachel Kaplan, Ph.D. was, in large part, responsible for and conducted the described socioeconomic analyses.

Appendix B

Synopsis of a Study Entitled "Effects of Freeway Noise on School Children"

Purpose:

To develop a criterion level for controlling noise from freeways (or other sources) in classrooms.

Method:

In the Los Angeles Unified School District, 20 schools have been selected for study. Half the schools are adjacent to freeways, while the "quiet" ten are not. Quiet schools are used for comparison.

In each school we are concerned only with the third and sixth grades because these grades, by law, are tested relatively extensively for academic achievement. In addition, State law also requires that the children now in grades three and six had their hearing checked the preceding year. Those children with hearing problems have been identified, and can be checked further if necessary.

Typically, we try to study all the third and sixth grades in each school. If this is not possible, the classes studied are selected so they are likely to be the noisiest (nearest the freeway) or quietest (furthest from a playground or noisy street, for example).

We spend three consecutive days in each classroom; hopefully the teacher involved is permanent and experienced at that grade level. In the classroom, we try to set up an observation point that approximates the location of those students who are furthest from the teacher at her/his usual operating position. Typically, the "usual operating position" is at the head of the class in front of the blackboard, from which point the teacher usually lectures the entire class.

Our observations consist of tape recording whatever happens in the classroom, including noise from freeways, airplanes, local streets, playgrounds, children in the classroom and the teacher. These tapes are subsequently analyzed to determine the noise level when certain classroom "events" occur, then the tapes are wiped clean for re-use in another classroom. The "events" are the times that (1) the observer cannot hear what is being said by the teacher or student, (2) the students are distracted by some noise, (3) the teacher rebukes students for not doing their work, or (4) classroom progress is interrupted or delayed while awaiting the cessation of some noisy event. The observer will be making notes on a form during the class. These notes describe what happened in the period and are used to facilitate analysis of the tape. A copy of the form is attached. You can see the forms associated with your class at any time.

A Final Note:

We are in no way evaluating teachers, teaching styles, or content. Please conduct your class as you usually do, ignoring the observer as much as possible. The observer will answer any questions you or the students may have.

Personnel:

Juanita Oñate

Robert Heald

Jerome Lukas

We are members of the Office of Noise Control of the California Department of Health Services.

Results of Monitoring of Noise and Air Quality in Feeder Areas of Schools at Various Proximities to Freeways

Jack W. Swing
California Office of Noise Control
Berkeley, California

Presented at the 98th Meeting of the
Acoustical Society of America
Salt Lake City, Utah

November 28, 1979

I would first like to present an overview of the project which is currently being conducted by Jerome Lukas and myself, and which is concerned with the effects of freeway noise on hearing levels and academic achievement of children. A preview of this study was presented at INTER-NOISE '78 in San Francisco, California.¹ The objectives of this larger study are outlined in Figure 1. The report which I am presenting today is concerned with the first objective, that of determining correlations between environmental noise levels, childrens' exposure levels, hearing loss and academic achievement. The other two items will be discussed in the final report on the entire project. (It is of interest that the State of California presently specifies a maximum intrusion level inside classrooms of 50 dB A-weighted. It is assumed that this maximum level is created by the noisiest vehicles on the road; i.e., heavy trucks.)

Figure 2 illustrates the various data elements which comprise the work efforts in the entire program. Four of these data elements are pertinent to today's discussion. These are: school site noise exposure, feeder area environmental noise, and air quality at both school sites and their surrounding feeder areas. This paper, then, is concerned with the environmental monitoring efforts in both noise and air quality which support the study on the effects of freeway noise on the academic performance of school children.

Figure 3 presents a map of the matched noisy and quiet school feeder areas which were incorporated in this study. Those areas shown in red are the high noise impacted schools and their feeder areas, while those in green are the socioeconomically matched quiet schools and their feeder areas. In total, there were 15 schools and their surrounding feeder areas involved in this study. Originally, 32 schools had been selected for preliminary analysis; this number was then reduced to a more manageable number. Of the 15 schools illustrated on the map, 8 of these were selected for air quality analysis. These schools are indicated by an asterisk adjacent to their feeder areas.

Figure 4 presents additional detail on two of the socioeconomically matched feeder areas that were utilized in this study, and serves to illustrate the general nature of the feeder areas providing children to our study schools. As may be observed, the two areas are in close proximity to each other, with the primary difference being that one area has considerably heavier freeway exposure than the other. The matching of areas has been carefully controlled for such

socioeconomic factors as ethnic population, mean housing values, mean income, percent employed, and other pertinent socioeconomic variables. An interesting item to observe in these two feeder areas is that in one case, school 8501,* there is clearly no freeway impact, while in the case of School 7412, a large portion of the feeder area has the Harbor Freeway running straight down the middle. However, off to the east is a segment of residential development well away from the freeway, whose individual noise environment is very close to that of the 8501 School feeder area. The analysis has been confined to those children which live in the immediate proximity of the schools they attend.

Figure 5 illustrates the scope of the monitoring efforts involved in this study. In the community noise monitoring aspects of the program, 15 school sites and their surrounding feeder areas were studied. This resulted in a total of 141 community noise monitoring sites which, at four to five days per site, yielded a monitoring effort of approximately 500 site days. Approximately 1,600 man-hours were expended on the community noise monitoring efforts. The air quality monitoring, which involved eight school sites, was conducted on a rotational basis during December 1978 and January and February of 1979. The monitoring involved measurements at each of eight schools on ten separate days. At each school site, outdoor lead and carbon monoxide were monitored for 24-hour periods. Indoor carbon monoxide was also monitored for two days at each of the schools during school hours.

In addition to fixed monitors at each school site, a fully-equipped air pollution monitoring van was rotated through the system and spent one entire 24-hour period at each of the school sites, thereby effectively replicating the air quality data taken on any given day at any given school site. Approximately 3,000 man-hours were expended in collecting the air quality data.

The personnel utilized for the noise monitoring efforts in this program were technicians from the California Division of Highways (CalTrans) who had little or no prior experience in noise monitoring. These technicians were, however, quite familiar with the air quality monitoring procedures and equipment. Each technician received approximately two hours training in community noise monitoring techniques prior to beginning the actual field monitoring work.

Given that the program would utilize personnel generally unfamiliar with community noise work, the equipment to be used had to be extremely simple, easy to use, reliable, and essentially foolproof. The Gen Rad Model 1945 Community Noise Analyzer was selected as generally fulfilling these requirements. Ten of these units were incorporated in the noise monitoring efforts, along with security boxes and Gen Rad weatherproof microphone systems. These consisted of installation of "pause" buttons on the devices, as well as reducing the run times by a factor of 3, such that we were able to conduct 10-minute samples rather than the normal sampling run time of 30 minutes. Throughout the duration of the noise monitoring, the Gen Rad units functioned reliably and maintained an operability rate on the order of 90% (i.e., 9 of the 10 were generally running and usable). Overall, less than 5% of all the data collected was either lost or invalidated. Most of these failures were due to operator error - such things as forgetting to set the unit to the proper run schedule, or the most common failure, allowing the unit to operate with insufficient battery voltage.

In addition to the Gen Rad units, two BBN Model 614 instruments were used for spot checks on the other data. These units were used exclusively by State Office of Noise Control personnel, because of their somewhat more sophisticated functional characteristics and higher value. The two BBN units functioned satisfactorily throughout the duration of the study.

I will next discuss the temporal sampling aspects of the study effort. Figure 6 illustrates the essential elements incorporated in selection of the community noise monitoring sites. The basic concept involved in site selection was taken from work done by Sutherland at Wyle Laboratories^{2,3} with modifications per R.K. Miller's techniques.^{4,5} Essentially, each school feeder area was identified (using Wyle's terminology) as the spatial sampling unit (SSU). Within each spatial sampling unit, a combination of systematic techniques (after Wyle) and

*In order to preserve confidentiality, schools are identified by code number only.

deterministic site selection processes (after Miller) were utilized. Only residential areas were monitored. These areas were selected in each feeder area by observing maps of each feeder area and, in most cases, driving through these areas to further subdivide the land uses. Each feeder area encompassed a physical area on the order of 1/4 to 1 square mile (.6 - 2.6 km²). Once the residential land use areas in each spatial sampling unit were identified, they were then subdivided into sub-areas of similar noise exposure, based on comparable proximities to freeways, major arterials, commercial strips, and industrial areas (deterministic subdivision). Typically 4-6 sites per spatial sampling unit were utilized. One may infer from Sutherland's analysis that this would yield a 95% confidence interval on the order of $\pm 4-5$ dB.

The next step was to secure specific measurement locations in each SSU. This involved locating a contact person in each feeder area. Generally, this contact person was the PTA president, the community representative, or the school principal. In some cases we found it useful, when time allowed, to address the PTA or parents' meeting, etc., in order to apprise them of our study efforts and the merit of our program towards improving the quality of education their children would receive. The contact person was responsible for providing names and addresses of interested parents residing in each of the identified sub-areas. The contact person would additionally make the initial personal contact with each prospective candidate and apprise them of the nature of the study. This approach yielded a more-or-less random site selection within each sub-area, which was, however, favorably biased in that each site utilized actually represented one of the school children's residences. Each candidate site was then visited and evaluated for suitability. The criteria for site suitability included the following: No dogs; safe, accessible microphone location; no construction in the immediate proximity of the site. Also, the particular site should not be dominated by any "unusual" noise sources (i.e., gas stations, car washes, dry cleaners, refrigeration compressors, should not be adjacent to delivery truck alleys behind markets, should not be near fire stations or hospitals, etc.). For those sites finally accepted for study, a contract was signed between the homeowner and CalTrans, in which the homeowner would receive \$5.00/day for the use of his premises. This amounted to an expenditure of approximately \$1,320 over the course of the study effort. We found, however, that these payments seemed to insure the cooperation and continued interest of the homeowner, who was also a parent of one of the children involved in the study. These individuals took sufficient interest in the program and in the security of the monitoring equipment, that losses due to theft were limited entirely to a single microphone.

When suitable candidate sites within a given SSU could not be located, it was necessary to substitute roving sites which were sampled on a rotational basis. In all cases we attempted to place the microphone as near the center lot as possible, with the provision that it also be located 20 feet (6.1m) or more from the nearest roadway and away from "high activity" areas around the home (swimming pools, air conditioning units, garages, patios, driveways, etc.). At the fixed sites, the microphone was typically mounted on a mast, 5 feet (1.5m) above the roof, either attached to a plumbing vent, chimney, TV antenna mast, or other means of support, at a typical elevation of 12-14 feet (3.7 - 4.3m). For the roving sites, the microphone height was typically 4-5 feet (1.2 - 1.5m), with its placement in the center of vacant lots in the study area. The generalized nature of the spatial sampling patterns is illustrated in Figure 7. In many cases, however, the ratio of fixed to roving or portable survey sites was other than as illustrated in this figure, due to the variables associated with selection of candidate sites and the general agreeability of the community to participate in the noise monitoring program.

In developing the temporal sampling strategies, again the work of Sutherland was incorporated.² The categories of sampling strategies considered in the program are illustrated in Figure 8. The temporal sampling schedules used in the noise survey are shown in Figure 9, and fall between Wyle's Class 2 and Class 3 measurements, in that nine sample periods per day were utilized at the fixed sites, which amounted to 19 hours of sampling for each 24-hour period. The roving site schedule typically followed Type Class 2 procedures, with monitoring at each site occurring for five to six 30-minute measurement sequences per 24-hour period. These sampling schedules were selected to allow the monitoring efforts to be conducted by two CalTrans technicians working on 8-hour overlapping schedules. In some instances it was necessary to modify

the roving site sampling schedule in order to achieve improved security for measurement personnel.

A sample data sheet for one of the fixed monitoring sites is illustrated in Figure 10. These data sheets have been keyed to the fixed location monitoring schedule of Figure 9 and are designed for use with the Gen Rad 1945 monitoring units. A sample preliminary data analysis control sheet, which illustrates the nature of temporal variations typically found at the fixed site noise monitoring locations, is shown in Figure 11. Equivalent energy levels were plotted as a function of time period and duration of sample for each of the community monitoring sites for each of the days which a particular site was sampled. Thus, after four to five days of monitoring a given site, a "typical" trend could be identified. Data lying clearly outside these "normal" trends were then further evaluated and spot checks were conducted at those sites having questionable data.

The preceding discussion dealt with a description of the spatial and temporal sampling considerations incorporated in the conduct of the noise monitoring efforts. I would next like to present some of the preliminary findings of both the air quality analysis and the community noise monitoring. First, let us consider the air quality data and the variations in air pollutant levels as a function of sampling date and freeway proximity of the measurement sites.

Figure 12 illustrates 24-hour outdoor airborne lead levels by school for each of the 10 sample dates. Three pairs of socioeconomically matched noisy and quiet schools are shown in this figure. As may be observed, all six schools illustrate almost identical trends in terms of lead concentrations as a function of their sample date. Proximity to freeways seems to have little or no effect on the values of the measured lead concentrations. Similar trends are also observed in the 24-hour average carbon monoxide levels at these same six schools for the same sampling dates, as shown in Figure 13. For these schools, again note that freeway proximity has little relevance on the levels of pollutants measured. In fact, almost identical trends as a function of sample dates are seen to exist between 24-hour lead levels and 24-hour carbon monoxide levels. Thus, based on these limited samples, we may conclude that air quality, certainly in the Los Angeles area, is primarily a basin phenomena and does not appear to be dependent upon proximity to a freeway.

Monitoring of interior carbon monoxide levels was also conducted at each of the eight school sites; however, interior levels appeared to show little or no correlation to exterior levels for the same measurement periods. Hence, no conclusions can be drawn at this time based on this study's data as to the effectiveness of the classroom building in lowering or at least otherwise affecting indoor carbon monoxide levels.

Finally, Figure 14 illustrates the temporal characteristics of the measured outdoor carbon monoxide levels for a particular school site. This figure, which is a combination of the data from all 10 sampling days, is quite typical in appearance to the other school sites, and illustrates an interesting phenomena; that during the hours of the day that school is in session, carbon monoxide levels tend to be at their lowest values.

Let me now present some preliminary results of the community noise monitoring. Figure 15 illustrates the average daytime noise exposure expressed in terms of L_{eq} for 8 hours for each of the school sites analyzed. As may be observed, the school sites are generally lumped into two distinct groupings; those in the immediate proximities to freeways, and those in the matched feeder areas away from freeways. The noise impacted school sites in general range from 5-6 dB louder than their quiet counterparts. However, it should be noted that the values represented in this figure are the logarithmic average of exposures at a particular school site, weighted by the number of rooms exposed to a particular level. For this analysis, a minimum of three measurements per school site were taken. These measurements were of the maximum exposed classrooms, minimum exposed classrooms, and the estimated average exposed classrooms. Thus, we could expect the overall range of exposures between noisy and matched quiet school sites to be considerably greater than are shown in this figure.

The day-night sound levels for the school feeder areas are summarized in Figure 16. For this initial analysis, the data has been stratified into freeway impacted and non-freeway exposed community sites. For a sample size of 22 freeway impacted sites, the mean value of observed day-night sound levels was 68.4 dB, with a standard deviation of 4.2. For the non-freeway sites (sample size of 82) the mean day-night sound level was 62 dB, with a sigma of 4.1. For all sites combined, the mean value was found to be 63.3, with an expected higher standard deviation of 4.9 dB. In subsequent analysis, the non-freeway sites will be further stratified in terms of their proximity to low volume local streets, high volume arterials, commercial strips, proximity to industrial areas, and single or multi-family housing units. It is anticipated that this further stratification of the non-freeway sites will yield standard deviations on the order of 2-1/2 - 3 dB.

Finally, the cumulative percentages of the populations in each of the feeder areas studied and their relative exposure to environmental noise (expressed in terms of day-night sound level) are summarized in Figure 17. For each school feeder area, the population exposure is expressed in terms of 10%, 50% and 90% levels, indicating that cumulative percentage of a feeder area's population exposed to a particular noise level. In addition to the measured data, we have shown the predicted ambient environmental noise levels based on population density, taken from BBN's 100 point study for the U.S. Environmental Protection Agency.⁶ Computation of this predicted exposure level in L_{dn} uses the following formulation:

$$L_{dn} = 10 (\log_{10} \rho) + 22, \text{ dB}$$

Where ρ is the population density in thousands of people per square mile.

For this analysis, population density was computed based upon the adjusted area within each school feeder area which reflected only residential land use. As may be observed, these predicted environmental noise levels, based solely on population density, covered a rather narrow range, that being from approximately 60 dB to 66 dB L_{dn} . (The population densities based on this adjusted area concept range from 7,100 people per square mile up to 21,000 persons per square mile.) It should be noted, however, that the BBN analysis was based on the assumption that the areas represented by it were not exposed to freeways or aircraft overflight activity. Therefore, applying such an analysis to the freeway noise impacted feeder areas may not be fully appropriate.

An interesting observation can be made looking at the range of populations exposed to the various environmental levels for matched pairs of school feeder areas. The mean, or 50% population exposed levels, do not vary significantly in any of the matched pairs of feeder areas. The range, however, for the freeway-exposed and non-freeway-exposed areas do show considerable spread, where in all cases, the freeway-exposed areas indicate a much higher range of environmental noise exposures. Ongoing analysis will include additional detail on the percentage of each feeder area's population exposed to environmental noise levels.

In conclusion, the purpose of this environmental monitoring has been to provide the supporting documentation needed to readily assess not only the school childrens' classroom noise environment, but the noise environment in which these children reside. This noise exposure information has been supplemented by air quality monitoring data in order that any adverse effects thought to be noise related can also be correlated with the air quality of the area in which the school is located and in which the children reside. We have been concerned, since the beginning of this project, that there may indeed be synergistic effects of combined high noise exposure and high levels of air pollutants experienced by those children residing near freeways. It would appear, at least from our initial analysis, that adverse effects found in these studies may be related solely to the noise exposure climate of the children, in that the air quality appears to be more or less constant throughout the portion of the Los Angeles Basin in which the study was conducted, and independent of freeway proximity.

EFFECTS OF FREEWAY NOISE ON SCHOOL CHILDREN

STUDY OBJECTIVES

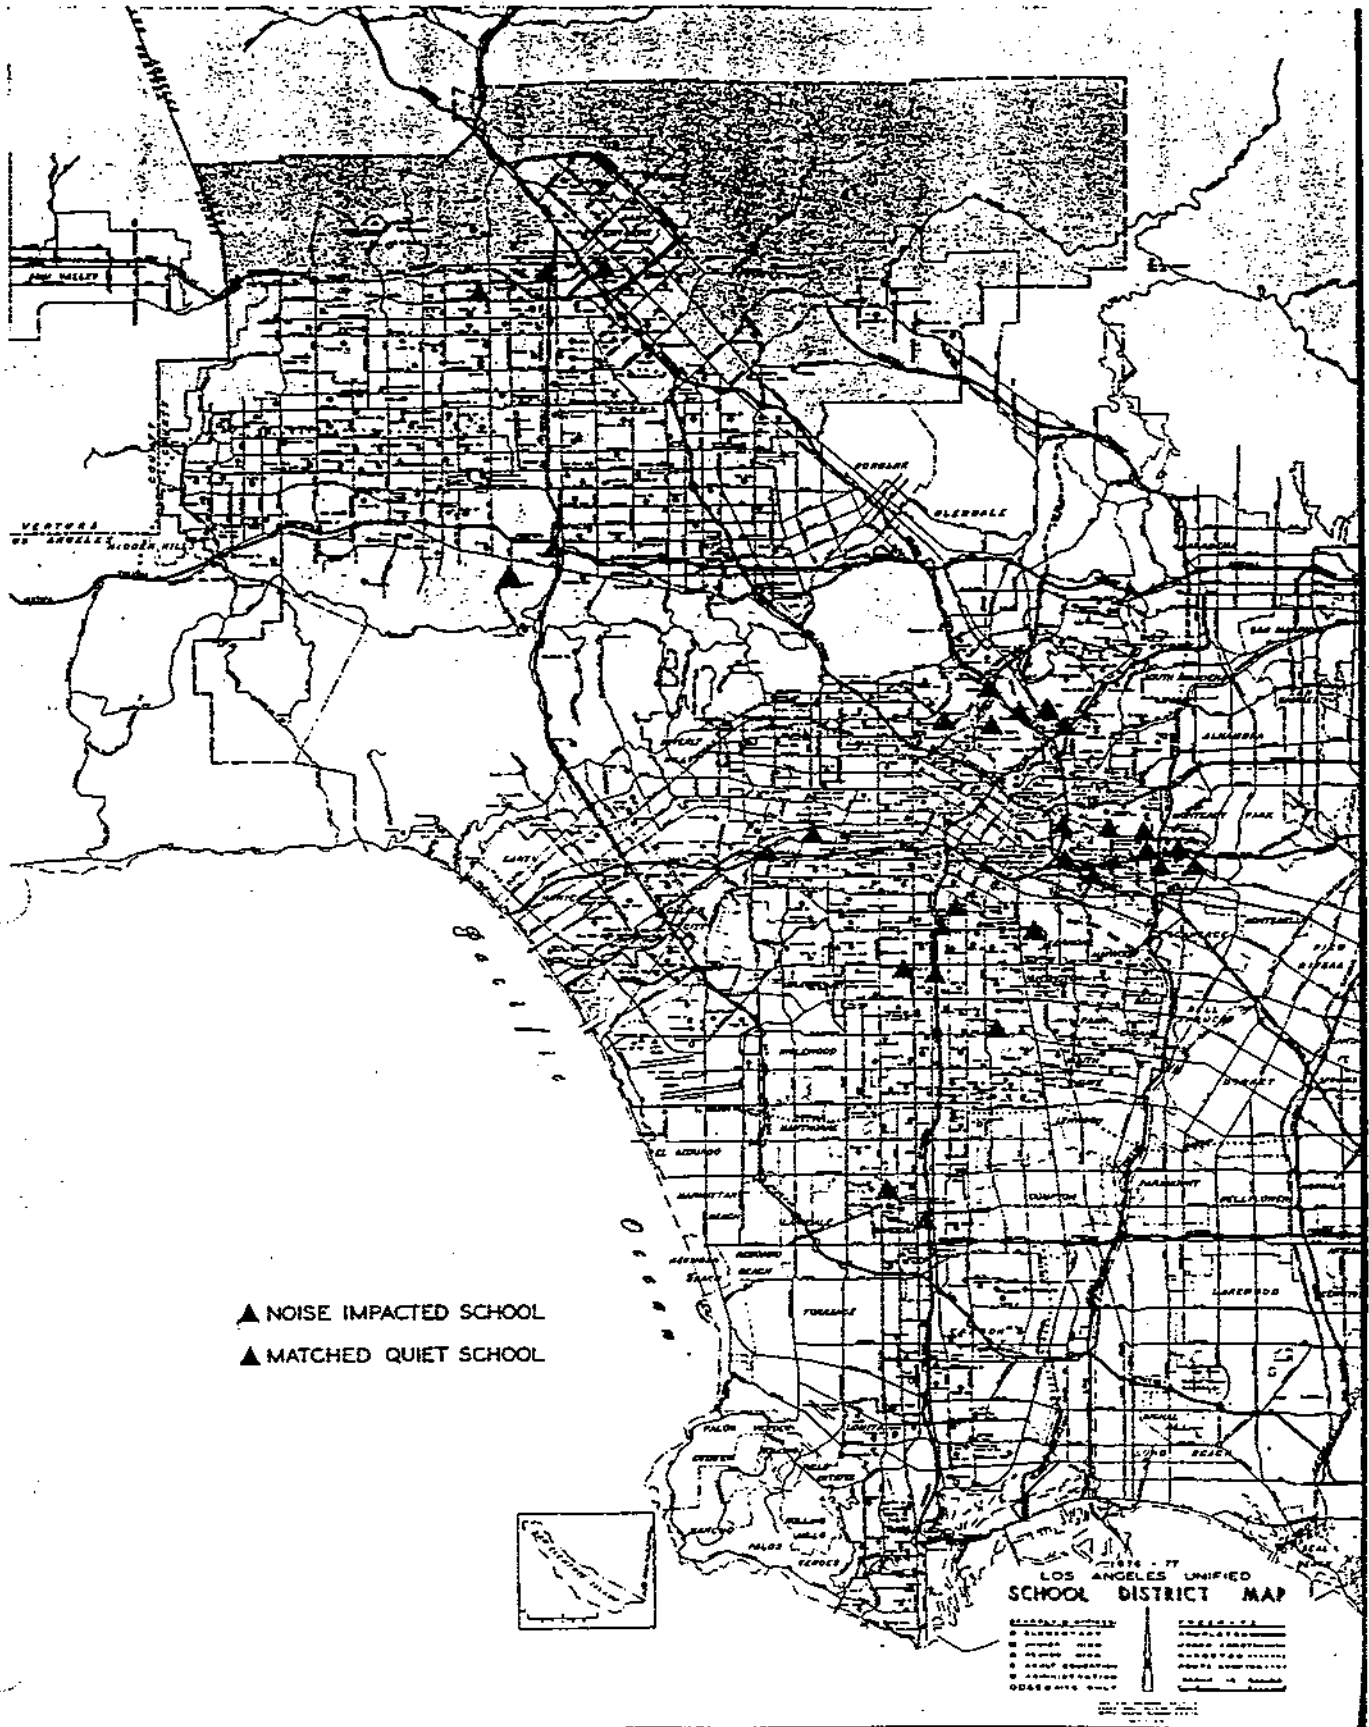

- DETERMINE CORRELATIONS BETWEEN ENVIRONMENTAL NOISE LEVELS, CHILDRENS' EXPOSURE LEVELS, HEARING LOSS AND ACADEMIC ACHIEVEMENT.
- DETERMINE THE DEGREE TO WHICH ENVIRONMENTAL NOISE MAY IMPEDE THE CLASSROOM PERFORMANCE OF TEACHERS AND STUDENTS.
- DEVELOP AN EMPIRICALLY BASED INTERIOR NOISE INTRUSION STANDARD FOR SCHOOL CLASSROOMS.

Appendix E

**Statement by Teacher for
Recording Normal Voice Level**

My name is *(state in full - e.g., Mrs. Harriet von Hobson)*. This is Room *(No.)* and the *(Number)* grade. This recording is to obtain a sample of the loudness of my voice. I normally speak to my entire class at this intensity.

Appendix F

Criteria for Use of Buttons During Classroom Observations

Note: All buttons must be held down for 1 second or more to insure an adequate electronic response.

Button Number

1. **Disregard:** Is for any event that is caused by "normal" sounds in the classroom. For example, school bell, paging a child or teacher over the school's intercom, visitors, library carts, etc.

Note: Children calling outside the classroom should not be a Disregard, particularly if such noise is distractive. Rather, it should be a Distract or Interrupt button.

Note: When any of the other buttons are pressed as a result of some internal (classroom) noise event, Disregard should be pushed immediately after releasing the other button in order to discriminate between external and internal noise events. On occasion this sequence was not followed; determination of the cause of "Can't Hear" or other event was discerned by listening to the tape.

Note: Fire and earthquake drills should be noted on written record.

2. **Can't Hear:** Is to be used when the observer is not able to hear and understand the teacher or student. The observer should use ears, not eyes, for this button - that is, do not attempt to lipread (the study is trying to estimate the percentage of time information cannot be heard or understood).

If the observer is unable to hear about 5 words or less, do not use Can't Hear button. If the observer is unable to hear or understand 6 or more consecutive words, push Can't Hear and hold until able to hear and understand. If unable to hear and press Can't Hear and the voice level increases, release Can't Hear and push Raise. Short answers (5 words or less) to questions that are not heard, for example, should be marked "Can't Hear".

3. **Rebuke:** Is to be used when the teacher calls the class or several individual students to order with or without a raised voice level. If noise was the cause, it should be possible to discern that from listening to the tape. Rebuke can be pushed as frequently as necessary, and should be held down until the class returns to order. Rebuke will vary with the teacher's particular style and will generally be of short duration. It may be: "Johnny!", "I'm waiting for quiet!", "I need attention!", etc. It may be silent - taking the child by the arm and walking to the hallway or outside the room.

4. **Interrupt/Pause:**

Interrupt: A 1-second press is to be used if the teacher or student stops an activity (talking, writing or reading) due to noise, and resumes the activity after the noise stops. The noise may be either internal or external in origin. The source of noise may be the freeway, airplane, helicopter, bus, fire truck, siren, etc.

Pause: Is 2 1-second presses to indicate a non-noise event, such as a student with a note from the office, a child being put in the hallway for discipline, students leaving to go to work in the cafeteria, etc. Use only if there is an obvious cessation of classroom activity.

5. **Distract:** Should be used in response to some external or internal event. When the children look around, fidget, or in some way lose their concentration, the **Distract** button should be pressed down and held for as long as necessary. **Distract** may be the result of a visitor - parent, teacher, principal, nurse, etc., entering the room. It may also be a loud or unusual noise from any source such as screech of brakes, freeway accident, car or truck "backfire", chair tipping over, microphone tipping over, breaking glass, etc. (N.B.: This event was observed very infrequently.) **Distract** may be followed by **Rebuke**.
6. **Raise** Is used if the teacher or student increases voice intensity. The increase may be in response to an increase in noise level from an internal or external source. It may be because one person is trying to get attention, children out for recess, or an increase in other external noise sources. **Raise** may be used after the fact and it is likely to be used that way. For example, voice level increases slowly, and consequently it may require some time before the voice level increases to the point the observer notices. When the teacher calls a single name at an increased level, push **Rebuke** rather than **Raise**. (N.B.: This event was almost never due to noise, rather it was associated with a "Rebuke".)
7. **Start/Stop:** To start an activity (recording period), push a variable number of times.

Aircraft Noise and Children: Longitudinal and Cross-Sectional Evidence on Adaptation to Noise and the Effectiveness of Noise Abatement

Sheldon Cohen
University of Oregon

David S. Krantz

University of California at Irvine

Daniel Stokols and Sheryl Kelly
University of California at Irvine

Longitudinal and cross-sectional data on effects of aircraft noise on elementary school children are presented as evidence for the effects of community noise on behavior. To examine the generality of previous laboratory findings in a naturalistic setting, the study assesses the impact of noise on attentional strategies, learned helplessness, performance on cognitive tasks, and blood pressure. Children were tested on the same measures twice, with a 1-year interval between sessions. A previous article reported cross-sectional findings from the first testing session. In the present article, longitudinal data are used to determine whether children *adapt* to the aircraft noise over the 1-year period and to assess the effectiveness of noise abatement interventions introduced in a number of noise-impacted classrooms. Additional cross-sectional data from the original testing session are also presented to provide further information on the utility of noise abatement. In general, there was little evidence for adaption to noise over the 1-year period. Noise abatement had small ameliorative effects on cognitive performance, children's ability to hear their teachers, and school achievement. The implications of the study for understanding the relationship between noise and behavior and resulting policy implications are discussed.

Although prolonged exposure to high-intensity noise can cause temporary and permanent losses of hearing (cf. Kryter, 1970), other general statements about the debilitating effects of routine noise exposure have to be made with considerably less confi-

dence. It is, of course, difficult to isolate the effects of a particular characteristic of a natural environment on the health and behavior of its occupants. Invariably the possibility exists that the people who choose (or are forced) to work or live in a noise-impacted environment are somehow different than those who work or live elsewhere. Moreover, environments that suffer from high levels of noise often have other characteristics (e.g., pollution, poor housing, high levels of population density) that may also deleteriously affect behavior and health.

In a recent article, Cohen, Evans, Krantz, and Stokols (1980) argue that the impact of noise (and other environmental factors) on health and behavior can best be assessed by a methodological strategy that combines the use of laboratory (experimental) and naturalistic studies. Laboratory studies direct our attention to categories of behavior and health that may be affected by noise and establish a causal link between noise and

The research reported in this article was supported by grants from the National Science Foundation (BNS 77-08576 and SOC 75-09224), the National Institute of Environmental Health Sciences (1 RO1 ESO176401 DBR), the Society for the Psychological Study of Social Issues, the University of Oregon Biomedical Fund, and the Uniformed Services School of Medicine (Clinical Investigation Grant 7208).

The authors are indebted to Laura Martin, Laurie Poore, Robyn Dawes, Jerry Lukas, Rich Haller, Ray Hyman, Nick Garshnek, the administrative staff, teachers, children, and parents of participating schools; the California Assessment Program; and the California Department of Health. We also wish to thank Michael Posner and Myron Rothbart for comments on an earlier draft.

these behaviors. Naturalistic research helps to establish whether particular effects found in the laboratory also occur in real-life settings. Cohen et al. (1980) argue that an interplay between these two approaches provides a more complete understanding of the relationship between environmental stressors and behavior and generates the type of data necessary to influence public policy.

Recent laboratory research on the impact of high-intensity noise has directed attention to the possible effects of community and industrial noise on a number of nonauditory systems. For example, noise is associated with alterations in task performance (cf. Broadbent, 1978; Loeb, 1979), decreased sensitivity to others (e.g., Cohen & Lezak, 1977; Mathews & Canon, 1975), and elevation of a number of nonspecific physiological responses (cf. Glass & Singer, 1972; Kryter, 1970). Exposure to noise that is unpredictable and uncontrollable can also result in *aftereffects*—deficits in performance and social sensitivity that occur after the noise is terminated (e.g., Glass & Singer, 1972; also see review by Cohen, 1980). The difficulty with this research is that it emphasizes acute rather than long-term noise effects. Thus, its implications for those suffering prolonged exposure in their homes or at work are unknown.

Although investigators have also begun to take a closer look at the nonauditory effects of noise in naturalistic settings (see reviews by Cohen, Glass, & Phillips, 1979; Kryter, 1970; Miller, 1974), methodologically tight studies are rare. This research also tends to be atheoretical and thus difficult to compare with existing laboratory work. Moreover, there are few *longitudinal* studies of people living and/or working under noise. Thus, it is unknown whether prolonged noise exposure results in increasingly deleterious effects or whether those exposed for prolonged periods adapt to noise, with effects disappearing after awhile. Studies comparing measures of health and behavior of the same person before exposure, immediately after exposure begins, and at set intervals for 1 or several years would allow us to determine the long-term course of stress and adaptation. In addition, longitudinal studies in situations in which the environmental stressor

is removed or attenuated would make it possible to determine whether there are long-term aftereffects of prolonged noise exposure.

Accordingly, this article reports data from the Los Angeles Noise Project—a longitudinal study of the impact of aircraft noise on elementary school children. The study was designed to examine the course of adaptation and the impact of a noise-abatement intervention on a variety of physiological, cognitive, and motivational measures. It is particularly concerned with exploring the generality of laboratory work on noise-induced shifts in attentional strategies, feelings of personal control, and nonauditory physiological responses related to health. (Findings from noise-induced laboratory exposure are discussed more fully in Cohen et al., 1980).

In this study elementary school children living and attending school under the air corridor of a busy metropolitan airport were compared with a matched group of children living in relatively quiet neighborhoods. In an earlier article, Cohen et al. (1980) reported cross-sectional data indicating that children from noisy schools had higher systolic and diastolic blood pressures than those from matched control schools and that this difference was greatest in children with the fewest years of exposure. Noisy-school children were also more likely to fail on a cognitive task and more likely to "give up" before the time to complete the task had elapsed. Finally, children from noisy schools who had lived in the neighborhood less than 2 years were less distractible than their quiet-school counterparts, whereas those children living under noise for more than 4 years were more distractible than those from quiet schools.

As part of a settlement of a law suit brought by the school systems against the airport, money was made available to lower the interior sound levels of many of the schools in the landing corridor. During the summer following the collection of data for the Cohen et al. article, architectural interventions were instituted in 43% of the noisy-school classrooms. These interventions resulted in a substantial decrease in noise levels in treated rooms (data presented later).

Thus, a large number of noisy-school children spent the following school year in noise-abated classrooms. At the end of the school year (1 year after original testing), children who were still enrolled in their schools (noisy and quiet) were retested on the original measures.

This article uses these longitudinal data and some previously unreported cross-sectional data from the first testing session to answer two questions about the long-term impact of aircraft noise on elementary school children. First, do children retested 1 year later continue to show effects found during the first testing session or do they *adapt* to the noise over the 1-year period? Cross-sectional data reported in the earlier article found some evidence for decreasing effects suggestive of physiological (blood pressure) habituation as duration of exposure increased, but failed to indicate adaptation of annoyance, cognitive performance, or helplessness. Second, what are the effects of noise abatement interventions in the classrooms on the various measures of health and behavior? That is, does assignment to a quieter classroom ameliorate the effects of noise?

Method

Overview of the Study

The subjects were children attending the four noisiest elementary schools in the air corridor of Los Angeles International Airport and three control (quiet) schools with similar (matched on social class and race) student bodies. Peak sound level readings in the noise schools are as high as 95 dB (A), and the schools are located in an air corridor that has over 300 overflights a day—approximately one flight every 2½ min. during school hours (Lane & Meecham, 1974). The study focuses on effects occurring *outside* of noise exposure. Thus, all tasks and questionnaires (except the achievement test records gathered from school files) were administered in a quiet setting—a noise-insulated trailer parked directly outside the school. Students were tested first in the spring of 1977 (T1) and again in the spring of 1978 (T2).

Tasks administered during the test periods were designed to assess feelings of personal control and to determine whether the children employed some common attentional coping strategies. Children were also asked a number of questions about their response to home and classroom noise and had their blood pressures measured. At the time of the first (but not the second) testing session, a parent questionnaire dealing with parent response to noise, mother's, and father's level of education, and the number of children in the family was sent home

with each child. Scores on standardized reading and math tests and data on absenteeism were also collected from school files at the time of the first (but not the second) session.

Data from subjects who were tested at both testing sessions (longitudinal data) were analyzed to determine if noise effects adapted—decreased or disappeared—over the 1-year interval between sessions. Separate analyses (both cross-sectional and longitudinal) were conducted to evaluate the effectiveness of the noise-abatement interventions. The cross-sectional data were collected during the first testing session and compared children who were in noise-abated classrooms with those in noisy (nonabated) rooms as well as those who were from quiet schools. The longitudinal analyses looked at the changes in the response of children who moved from a noisy to a noise-abated classroom in contrast to those children who spent both years in noise-impacted rooms.

This section will provide short descriptions of the experimental tasks and procedures. The reader is referred to Cohen et al. (1980) for additional detail.

Matching

Three control schools (quiet schools) were matched with the experimental schools for grade level, ethnic and racial distribution of children, the percentage of children whose families are receiving assistance under the Aid to Families With Dependent Children program, and the occupations and educational levels of parents. (Detailed data on matching are reported in Cohen et al., 1980). Thus, we were able to compare samples of children attending noisy and quiet schools who were relatively similar in terms of age, social class, and race. A regression analysis procedure (described later) allowed additional control over these factors.

Subjects

The study included children from all noise-impacted third- and fourth- grade classrooms in each noisy school as well as children from an equivalent number of classrooms in quiet schools. To assure that performance differences between children from noisy and quiet schools could not be attributed to noise-induced losses in hearing sensitivity, children failing (either ear) an audiometric pure tone threshold screening (500, 1000, 2000, 4000 Hz at 25 dB) were not included in the study. Six percent of the noisy-school and 7% of the quiet-school children failed the screening.

Noise Measures

Testing session 1: Interior sound levels (without children) were measured inside each classroom with Traoustics Sound Level Meters (SLM S2A). Peak decibel level (A scale) was recorded during 1-hour sessions in both the morning and afternoon. It is important to note that due to limitations in the equipment and duration of the measurement, these measures are presented only to establish *relative* differences between the sound levels of various types of classrooms, not as evidence for sound-level criterion or threshold levels of effects.

Testing session 2: Sound levels (again without chil-

dren) were measured inside each classroom for 1 hour during the morning and 1 hour during the afternoon with Digital Acoustics (DA605), B and K (4426), and General Radio (1945) noise-level analyzers.¹ The machines were calibrated to a pure tone source every other day and were periodically calibrated against one another to ensure intermachine reliability. Microphones were placed approximately 3 feet (.9 m) from the ground in the center of the room. Data available from all machines included peak decibel level (A scale), the decibel level exceeded 33% of the time (L_{33}), and the noise level averaged on an energy basis over each hour period (L_{EQ}).

Parent and Child Questionnaires

The questionnaire administered to each child assessed his/her perception of classroom and home noise levels. The parent questionnaire (T1 only) also included questions on perception of home noise level as well as queries as to how long the child had been enrolled in his/her school and how long she/he had lived at the present address. Data on school enrollment were also available from school files.

Blood Pressure and Health

Each child's resting blood pressure (systolic and diastolic) was taken each testing day on an SR-2 Physiometrics automated blood pressure recorder.² Blood pressure data are based on the mean systolic and diastolic pressures for these two measurements. The graphic output of the machine was coded after the study was completed, with coders blind to experimental condition. Each child's height and weight were also measured. Absenteeism was used as an indirect measure of health, since absence from school is often attributable to illness. These data were available from school files.

Helplessness

Performance on a cognitive task preceded by a success or failure experience was employed to examine the effect of noise on response to failure and on persistence on a difficult task. Response to failure is a standard measure of susceptibility to helplessness (cf. Seligman, 1975). Thus, if noisy-school children are more susceptible to helplessness, they will show greater effects of a failure experience than their quiet-school counterparts. A lack of persistence ("giving up" syndrome) is considered a direct manifestation of helplessness.

First testing session. Each child was given a treatment puzzle to assemble after the tester demonstrated the task with another puzzle. One half of the children received an insoluble (failure) puzzle and one half a soluble (success) puzzle. The soluble puzzle was a circle, and the insoluble puzzle was a triangle. After time (2½ min.) was up on the first puzzle, the child was given a second, moderately difficult puzzle to solve. The second (test) puzzle was the same—a square—for all (success and failure) children. The child was allowed 4 min. to solve the second puzzle. Whether the puzzle was solved, how long the solution took, and whether the child "gave up" before the 4 min. had elapsed were used as measures of helplessness.

Second testing session. Treatment puzzles were not readministered during the second session. Each child was given only the test (square) puzzle to solve. As previously, the child was allowed 4 min. to solve the test puzzle, with the same measures of helplessness assessed as in the earlier testing session.

During T1, a large proportion (34%) of the children assigned to the success condition who received a soluble treatment puzzle failed to solve the treatment puzzle within the 2½ min. allowed. Although the fact that a number of children self-selected themselves into a failure condition makes it difficult to interpret main effects for success-failure and interactions between success-failure and noise, comparisons between the children from noisy and quiet schools, irrespective of (controlling for) their pretreatment, are of primary interest.

Distractibility

It was proposed in our earlier article (Cohen et al., 1980) that children reared in noisy environments become inattentive to acoustic cues (cf. Cohen, Glass, & Singer, 1973; Deutsch, 1964). Since children who are relatively inattentive to acoustic cues should be less affected by an auditory distractor, distractibility was used as a measure of this selective inattention. Subjects performed a crossing out *Es* task under both ambient and distracting conditions. The subject's task was to cross out the *Es* in a 2-page passage from a sixth-grade reader. Each subject worked on a short practice paragraph and then on the task for 2 min. Two versions (different samples of prose) were used.

In a distraction condition, the child worked on one of the versions of the task while a tape recording of a male voice reading a story was presented at a moderate volume over headphones. In the no-distraction condition, the alternative form of the task was completed with headphones on but under ambient sound conditions. The distraction and no-distraction tasks were administered on different testing days. Both the order of alternative versions of the task and the experimental conditions were counterbalanced. The criterion measure was performance (percentage of *Es* found) on the distraction task after these scores were adjusted for no-distraction performance. It was expected that children from noisy schools would be less affected by distraction.

¹ The noise-level analyzers, which were not available to us during the first testing session, were used during the second session because of their increased sensitivity and accuracy and their ability to provide various measures of noise over time, for example, L_{EQ} and L_{33} . It is, however, appropriate to again caution the reader that the rather short interval of measurement limits the use of these data to the establishment of relative sound levels of classrooms in the various conditions.

² This instrument is an electronic infrasonic device that records on a rotating paper disc. Measurements were taken with a rubber cuff entirely encircling the upper arm. The reliability of this device for blood pressure measurement in children has been established in previous work (e.g., Voors, Foster, Frerichs, Weber, & Berenson, 1976).

Table 1
Overview of the Analyses

Title of analysis	Sample	Classroom noise condition		Additional independent variable/conditions
		1977 (T1)	1978 (T2)	
I. Attrition bias	T1	Noise vs. quiet		Retested at T2? Yes No None
II. Adaptation to noise	Attrition (T1 & T2)	Noise* ——— Noise vs. Quiet ——— Quiet		
III. Blood pressure: Habituation or attrition?	T1	Noise vs. quiet		Migration Not enrolled in school 1 year after T1 vs. Enrolled in school 1 year after T1 but not 2 years later vs. Still enrolled 2 years after T1 None
IV. Noise abatement: Cross-sectional analyses	T1	Noise vs. abated vs. quiet		None
V. Noise abatement: Longitudinal analyses	Attrition (T1 & T2)	Noise ——— Noise vs. Noise ——— Abated		None

* The few classrooms that had had noise-abatement work completed prior to T1 are included as noisy classrooms in these analyses. This was done in order to make these analyses comparable to those reported in Cohen et al. (1980) and is justified by the findings reported in this article suggesting little if any effect of abatement.

School Achievement

The scores on the California Test of Basic Skills (California Assessment Program, 1976) reading and math tests (administered during the second and third grades by the school system) were gathered from school files, and the Wepman (1958) auditory discrimination test was administered individually to children in the soundproof van. The Wepman test measures the child's ability to discriminate between pairs of words that differ from each other in either initial or final sound, for example, "sick-thick" or "map-nap."

To roughly equate the effect of the noise and quiet conditions on the aptitude of the children at the time they entered school, analyses of school achievement and auditory discrimination scores included an additional control for the mean cognitive abilities (standardized test administered by school) of the child's class on entering the first grade.

Analyzing and Interpreting Data

The answers to our questions about adaptation to noise and abatement effectiveness each require different blockings (or groupings) of the noise variable and analyses of different subsets of the sample. Table 1 provides an overview of these analyses. It may be useful for readers to refer to this table while reading the results sections of the article.

To avoid confusion about exactly which analysis and/or data set is being employed at any point, we will present two consecutive sets of results and discussions. The first will examine the question of adaptation and the second the question of the effectiveness of the noise-abatement interventions. These sets will be followed by a short section on the overall implications of the study.

The general statistical model (described below) was used in all data analyses reported in this article. Biases in subject attrition (also described below) are important in aiding interpretation of all longitudinal analyses. Attrition bias is not an issue in the interpretation of cross-sectional analyses, which involve only T1 data and thus include the entire T1 sample.

Statistical analyses. A regression technique was used in all the analyses reported in this article to allow additional control over the effects of socioeconomic and demographic factors (cf. J. Cohen & Cohen, 1975). All data analyses include controls for the number of children in the child's family, grade in school, months enrolled in school, and race. These control factors, forced into the regression first, are then followed by noise, and then the interaction between noise and months enrolled in school.³ Additional controls are used in the analyses of

³ To avoid confusion, the reader should note that two distinct terms are used to refer to different time frames. T1 and T2 refer, respectively, to the first and second testing sessions, separated by 1 year. The term "months

blood pressure (height and ponderosity), school achievement (cognitive aptitude test), and distractibility (performance under ambient conditions). The primary helplessness analyses include factors for success-failure and the interaction between success-failure and noise. (Those who solved and those who did not solve the success treatment puzzle are treated as separate groups.) Analyses of longitudinal data also include a repeated measure factor (Testing Session 1, Testing Session 2).⁴ School achievement analyses were performed with classrooms (nested in noise) rather than with individual children, as the unit of analysis. A more detailed description of the form of each analysis is provided in Cohen et al. (1980).

The various measures were analyzed in predetermined multivariate clusters created on the basis of theoretical consideration.⁵ This form of analysis helps to decrease the probability of chance findings that occur when a large number of analyses are necessary (cf. Bock, 1975).

Interpreting longitudinal analyses: Sample attrition bias. An effort was made to retest all students who were attending school during the longitudinal follow-up. Sixty-two percent (163: 83 noise and 80 quiet) of the original sample (262: 142 noise and 120 quiet) were retested. Although a slightly higher proportion of quiet-(67%) than noisy-(58%) school children were retested, this difference was not statistically significant, $\chi^2(1) = 1.99, p < .16$.

All data analyses that include data from the second testing session (these are all repeated measures designs) were based on the 163 retested students—the *attrition sample*. Sample attrition (not being retested) may be attributable to either migration or absenteeism. It is our purpose at this point in the article to describe the nature of any self-selection bias in the retest sample; thus, these causes of attrition are not separated.

The purpose of the attrition bias analyses was to determine whether remaining in the study (being retested) was correlated with one or more of the criterion variables in one of the study's conditions (noise or quiet) but not in the other. For example, noisy-school children who were *not* retested had higher blood pressures than those who were retested; whereas being retested was unrelated to blood pressure for quiet-school children. This particular attrition bias resulted in a deflated mean blood pressure for noisy-school children in analyses of the attrition sample. As a result, there is a lessening of the difference between mean blood pressures of noisy- and quiet-school children. It is important to note cases in which the lack of a main effect for noise in the attrition sample is due to selective attrition as opposed to adaptation to noise or problems with measure reliability. To determine whether any such biases occurred, data from the first testing session (all of the original 262 subjects) were analyzed with whether a student was retested (yes/no), and a Retest \times Noise interaction added to the standard analysis (see Table 1, I). Note that these analyses are not presented in an attempt to make any conclusions about those who were retested versus those who were not but only to provide information about the nature of the attrition bias that may be useful in interpreting anal-

enrolled in school" refers independently to the length of time the child was enrolled in school at T1.

yses presented later in this article. For this reason, a rather liberal alpha level (.10) was employed, and multivariate analysis is not reported.

A retest bias occurred on a number of the dependent variables. On all of these variables, those in the noise condition who showed the greatest stress during T1 were not present at T2. No such relationship (or in some cases a slight reversal) existed in the quiet group. The variables with Noise \times Retest interactions suggesting this pattern were the child's perception that noise made it difficult to hear their teacher, $F(1, 241) = 3.46, p < .06$, and systolic, $F(1, 233) = 8.65, p < .004$, and diastolic, $F(1, 233) = 3.39, p < .07$, blood pressure.

Adaptation to Noise

Results

To determine whether or not the children adapted to the noise over the 1-year period, data from the attrition sample (those who were tested at both T1 and T2) were analyzed in a repeated measures design, with Testing Sessions 1 and 2 constituting the repeated measure (see Table 1, II). The occurrence of the same difference between noise and quiet schools at both T1 and T2 (main effect for noise) provides evidence for test-retest stability. A diminution of the T1 difference between noise and quiet at T2 (Noise \times Testing Session interaction) suggests the possibility of progressive adaptation to the noise stressor. Finally, an increased difference between noise and quiet at T2 (Noise \times Testing Session interaction) suggests that increased exposure results in an increased effect of noise.

It is important to note that these analyses include only the attrition sample (163), that is, those who were enrolled and present during the second testing session. Thus, vari-

⁴ Two new variables, sum (T1 + T2) and difference or change score (T1 - T2), were created for each dependent variable. Then separate regression analyses were conducted on each of the new variables. Analyses of the sum score reflect differences between groups, irrespective of the testing session, whereas analyses of change scores reflect differences between testing sessions over groups. The results of these analyses are mathematically equivalent to a standard repeated measures analysis with two levels of the repeated measure (cf. Overall & Klett, 1972).

⁵ There are separate clusters for general health, blood pressure, helplessness, and the child questionnaire. The distraction analyses were run as univariates, since each analysis required a unique control factor.

ables that were related to attrition for noisy-school (but not quiet-school) children, including the child's perception of classroom noise and the blood pressure measures, are unlikely to show noise effects in this analysis.

Children's perceptions of noise. Main effects of noise for children's reports of how much airplane noise bothered them at home, $F(1, 145) = 3.62, p < .05$, and in the classroom, $F(1, 145) = 15.74, p < .001$, suggest that those attending noisy schools report high levels at both testing sessions. There was no effect on the remaining child questions. The multivariate noise effect was significant, $F(7, 139) = 3.13, p < .004$.

These results are generally consistent with those reported in the original study (analyses including the entire sample of children tested at T1) in which noisy-school children reported noisier classrooms (a variable affected by attrition bias in the present analysis) and said that airplane noise bothered them more in both home and classroom.

Health measures. Although neither height nor weight were significantly related to noise in the entire T1 sample, noisy-school children did attend school more often than their quiet-school counterparts. In the present analysis, there was a Noise \times Testing Session effect for the percentage of days attending school, $F(1, 120) = 8.00, p < .005$. Although noisy-school children had better attendance during the year of the first testing session (98% attendance for noise group versus 96% for quiet), the attendance of noisy- and quiet-school children was equivalent (94% for both groups) during the following year. The multivariate for the interaction effect of Noise \times Testing Session was significant, $F(3, 118) = 3.71, p < .01$.

Blood pressure. Although the analysis of the complete T1 sample indicated inflated systolic and diastolic blood pressure for noisy-school children, there were no effects of noise, testing session, or any of the interactions on either systolic or diastolic blood pressure in the present analysis. Longitudinal blood pressure effects were not expected, however, since a relatively high proportion of noisy-school children with high blood pressure were lost to attrition and thus were not included in the present analyses.

Distractibility. In the earlier report of

Figure 1. Distractibility at T1 and at T2 as a function of school noise level and duration of exposure. (Each period on the number of year's of exposure coordinate represents one quarter (based on quartiles) of the sample. For example, 25% of the sample were enrolled in school for less than 2 years.)

the entire T1 sample (Cohen et al., 1980), an interaction was found between noise and months enrolled in school for the percentage of Es found on the distraction task. Children in noisy schools did better than the quiet group on the distraction task during the first 2 years of exposure and worse after 4 years. Quiet- and noisy-school children who had been enrolled between 2 and 4 years, demonstrated equivalent performance. As apparent from the lower half of Figure 1, the attrition sample showed a similar T1 pattern, except that noisy-school children, who had been enrolled for 2-4 years also appeared to be less distractible than their quiet-school counterparts. Examination of the upper half of Figure 1 indicates that the T2 sample continues to show the same pattern of better performance by the noise group on the distraction during the earlier years. In this case, however, performances of the noisy-school and quiet-school groups are rather equivalent after 4 years of enrollment—Noise \times Months interaction, $F(1, 141) = 3.66, p < .06$.

Helplessness. As in the analysis of the entire T1 sample, there are effects of noise on test puzzle performance that occur irre-

spective of whether the child received a success (solved or not) or failure treatment. Noisy-school children were more likely to fail the test puzzle than quiet-school children, $F(1, 133) = 5.37, p < .02$, and more likely to take longer solving the puzzle, $F(1, 133) = 2.88, p < .09$, than quiet-school children—multivariate effect for noise, $F(3, 133) = 1.92, p < .12$. Although differences between proportion of children failing and time to solution were stable across the two testing sessions, quiet/noise differences in the percentage of children giving up occurred only at T1—Noise \times Testing Session interaction, $F(1, 133) = 3.90, p < .05$. The multivariate effect for the Noise \times Testing Session interaction was not, however, significant, $F(3, 131) = 1.57, p < .20$.

As pointed out in Cohen et al. (1980), an analysis of the proportion of children giving up that includes only those children who failed the test puzzle provides the most direct measure of helplessness. This analysis looks at the degree to which failure is associated with giving up as opposed to unsuccessful persistence. Although data for the entire T1 sample indicated increased giving up on the part of noisy-school as opposed to quiet-school children, there was neither a noise nor Noise \times Testing Session interaction in the present analysis.

Although not directly relevant to problems posed in this article, it is of general interest to examine whether the soluble or insoluble puzzle given at T1 affected performance on the test puzzle administered 1 year later, irrespective of (i.e., controlling for) noise exposure. This comparison provides a rough measure of the duration of the learned helplessness effect. That is, does a failure as opposed to a success pretreatment affect subsequent task performance as much as a year later? As suggested earlier, because of a selection bias created by subjects who were assigned to a soluble puzzle condition who failed to solve their soluble puzzle, there were three levels of the success-failure factor: success group who solved their pretreatment puzzle, success group who failed their pretreatment puzzle, and failure group. At both T1 and T2, children who received a success treatment puzzle and solved that puzzle were more likely to solve, $F(2,$

133) = 5.39, $p < .006$, and faster at solving the test puzzle, $F(2, 133) = 3.16, p < .05$, than both those who failed to solve the success treatment puzzle and those who received a failure treatment puzzle. There were no differences between these conditions on the proportion of children giving up; multivariate for success-failure, $F(6, 262) = 2.16, p < .05$. These data suggest the possibility of a helplessness effect persisting over a 1-year period, but they are difficult to interpret because of the self-selection problem.

Discussion

In general, the retest data provide strong support for the stability of the effect of noise on annoyance, distractibility, and performance on a moderately difficult task. First, at both testing sessions, noisy-school children were bothered more by aircraft noise than quiet-school children in both the classrooms and homes. Second, the similarity of the T1 and T2 data on the distraction task suggests the relative stability of this unpredicted interaction. Specifically, it suggests that there is some initial increased ability among noise-impacted children for "tuning out" auditory distraction and that this advantage disappears after 4 years of exposure. It was suggested in the earlier article that the children initially attempt to cope with the noise by tuning it out. Later, however, as they find that the strategy is not adequate, they give it up. An alternative explanation is that as duration of exposure increases, the children become more discriminating in terms of the kinds of sounds that they tune out. That is, initially they tune out wide range of acoustic stimuli (including the distractor used in the present study, which is dissimilar to aircraft noise), but later they tune out only sounds that are similar to the aircraft noise.

The present analyses also suggest that noisy-school children were poorer than quiet-school children at solving the test puzzle at both testing sessions. However, the increased "giving up" on the part of the noisy, as opposed to quiet-school children found in the analysis of the entire T1 sample was not found in the present analysis. The lack of

such an effect may have occurred because of subject attrition, because the children had had a previous experience with the same puzzle, or because the effect disappeared, that is, adapted out over time. It should be noted that the cross-sectional analysis of the entire T1 sample *did not* indicate a lessening of giving up with increased months of school enrollment. This suggests that the giving up effect does not adapt out over time.

Although the previously reported differences between the noisy- and quiet-school children on systolic and diastolic blood pressure were not found in the analysis of the attrition sample, this result was expected, given the large proportion of noisy-school children with high levels of blood pressure who were not retested. Because of this, the lack of a relationship between noise and blood pressure (at either T1 or T2) in the attrition sample *does not* constitute information for the acceptance or rejection of the hypothesis that the children adapted to noise.

A piece of data that was rather inconsistent with other findings in the original study of the entire T1 sample was that noisy-school children attended school more often than quiet-school children. The present data suggest that this difference did not exist for the data collected at T2. We are unable to explain the difference that occurred at T1 and feel that it may reflect random fluctuation, with T2 reflecting a regression to the mean.

In sum, the data suggest that effects related to living and attending school in a noisy neighborhood are stable over a 1-year period. That is, there is little evidence for adaptation to the noise.

Blood pressure: Habituation or attrition? The cross-sectional analysis of the entire T1 sample reported in an earlier article (Cohen et al., 1980) similarly found little evidence for adaptation. In fact, the only data supporting an adaptation hypothesis was the finding that systolic blood pressure differences between noisy- and quiet-school children (noisy-school children had higher blood pressure) were greater during the first few years of school enrollment. A similar pattern also occurred for diastolic pressure, although it did not reach statistical significance. (Figure 2 depicts the results of

Figure 2. Systolic and diastolic blood pressure as a function of school noise level and duration of exposure. Each period on the number of years of exposure coordinate represents one quarter (based on quartiles) of the sample. For example, 25% of the sample were enrolled in school for less than 2 years. (From "Physiological, Motivational, and Cognitive Effects of Aircraft Noise on Children: Moving from the Laboratory to the Field" by Sheldon Cohen, Gary W. Evans, David S. Krantz, and Daniel Stokols, *American Psychologist*, 1980, 35, 231-243. Copyright 1980 by the American Psychological Association. Reprinted by permission.)

the T1 sample analysis, as reported in Cohen et al., 1980.) As previously suggested, this effect could be due to noisy-school children adapting to the stressor as the duration of exposure increased. On the other hand, the effect could be due to some kind of subject selection bias. That is, children with noise-induced, elevated blood pressure may have quickly moved out of the noise-impacted neighborhood and thus lessened the mean blood pressure for noisy-school children in the 2 or more years of exposure categories.

Some longitudinal data on how long specific noisy- and quiet-school children remain enrolled in their schools can help distinguish between these two explanations. The attrition bias analyses reported earlier suggest the possibility that people who move out of noise-impacted neighborhoods are different than those who move out of similar neighborhoods not suffering from noise pollution. Conclusions of this kind cannot, however, be

made from the attrition analyses, since a subject assigned to the not-present-during-retesting category may have moved or may have merely been absent during the retesting session. Thus, a second analysis of T1 blood pressure data was conducted to determine whether families of noisy-school children who showed elevated blood pressure were more likely to *move* sometime during the 2 years following the original testing session than families of quiet-school children and of noisy-school children not showing elevated pressure. In this case, unlike the attrition analyses, children who were absent at T2 but still enrolled were categorized as attending school. The retest factor used in the attrition analysis was replaced with a three-level measure of *migration* (not enrolled in school after 1 year/enrolled 1 year later but not after 2 years/still enrolled after 2 years, see Table 1, III).

As in the attrition bias section, we are concerned primarily with the Noise \times Migration interaction. This interaction suggests that those children leaving the noise-impacted neighborhood have different scores on blood pressure than those leaving the quiet neighborhood. As depicted in Figure 3, noisy-school students with the highest blood pressures move out of the noise area soon (within 2 years) after the initial testing: $F(2, 229) = 6.80, p < .001$, for systolic, and $F(2, 229) = 3.50, p < .03$, for diastolic. The multivariate interaction effect was significant, $F(4, 456) = 3.84, p < .004$. Thus, it appears that selective attrition, *not* adaptation, is responsible for the decrease of the difference between the blood pressure of noisy-school and quiet-school children.

Apparently the families of those noise-group children who showed elevated blood pressure were more likely to move out of the noise-impacted neighborhood than the families of children who did not show elevated blood pressure. It is important to emphasize that these effects occurred with race and social class partialled out of the analyses and that this bias for those with higher blood pressure to move out of the neighborhood occurred only in the noise-impacted area. Some possible explanations for this effect are that (a) parents of children with elevated blood pressure were sensitive to their chil-

dren's experience of stress and as a consequence moved to a less noisy neighborhood; (b) because of a familial bias (either genetic or environmentally determined), parents of children with noise-induced blood pressure elevations experienced similar stress-related reactions that motivated them to move from the neighborhood; (c) the children's elevated blood pressures were a response not to the noise itself but to their parents' own noise-induced stress, which was motivating the parents to move from the neighborhood; and (d) some unknown third factor is related to mobility, high blood pressure, and living in a noisy neighborhood.⁶

Noise-Abatement and Noise-Stress Reduction

Do noise-abatement interventions (and their resulting reduction in classroom noise level) decrease or ameliorate the effects of noise in impacted classrooms? Both cross-sectional data collected during the first testing session and longitudinal data looking at changes in the responses of children who moved from noisy to quiet classrooms are relevant to this question. As in the previous section, longitudinal data are based on the attrition (163) sample and, thus, are subject to the attrition bias. The cross-sectional data reported in this section are based on the entire T1 sample (262).

⁶ The explanations that suggest that high blood pressure is the *cause* of the migration from the noisy neighborhoods assume that the child and/or parent perceive that the child is under stress. It is probable that only those children with blood pressures substantially higher than the group mean would fit into this category. Thus, if elevated blood pressure is responsible for increased migration in the noisy neighborhoods, large proportions of those children leaving the noisy neighborhood would have relatively high blood pressures. Analyses of the proportion of children moving from their neighborhoods as a function of whether they attend a noisy or quiet school and whether they have high (80th percentile or above) or low (below the 80th percentile) blood pressure indicate that the proportion of children with high blood pressure who move from the noisy neighborhoods is higher than the proportion of high blood pressure children who move from quiet neighborhoods (Noise \times Blood Pressure interactions: for systolic, $F(1, 246) = 5.42, p < .02$; for diastolic, $F(1, 246) = 5.59, p < .02$). Apparently, a relatively large number of noisy-school children who move do have substantially elevated blood pressure.

Results: Cross-Sectional Analyses

Several of the classrooms in noise-impacted schools had been treated with noise-reducing materials several years before the first testing session. Because they were still relatively noisier than quiet comparison classrooms and because of the presumption that the high noise levels in the homes and play areas of noisy-school children were as important as the actual classroom level, these treated classrooms were not separated from other noisy school classrooms in the previous article (Cohen et al., 1980). To evaluate the effectiveness of this treatment and assess the relative impact of a somewhat quieter classroom on the criterion variables, data from the first testing session were reanalyzed, with classrooms categorized as noisy (97 children), abated (45), and quiet (120). The regression analyses on criterion variables are identical to those described previously except that the noise variable had the three levels described above instead of two. (see Table 1, IV).

Noise measures. The mean peak noise level for noisy classrooms was 79.06 dB, for abated classrooms it was 63.17 dB, and for quiet classrooms, 56.60 dB. An analysis of variance indicated a significant difference between these means, $F(2, 34) = 38.45$, $p < .001$. Moreover, preplanned contrast indicated significant differences between noise and quiet, $F(1, 34) = 75.06$, $p < .001$; quiet and abated, $F(1, 34) = 16.93$, $p < .0002$; and noise and abated, $F(1, 34) = 45.89$, $p < .0001$, rooms. In general, it was expected that effects on criterion variables would be directly related to average classroom noise levels and therefore, the mean values would fall in the following order: noise, abated, quiet. Preplanned comparisons reported in this section were employed to directly test this hypothesis.

Child questionnaire. Although noise had a significant impact on children's self-reports of classroom noise, $F(2, 249) = 2.69$, $p < .07$; airplane disturbance in the classroom $F(2, 249) = 7.4$, $p < .0008$; and airplane disturbance at home, $F(2, 249) = 7.78$, $p < .0005$, all reflected a relatively low level of noise annoyance among quiet-classroom children as compared with noisy- and abated-

Figure 3. Systolic and diastolic blood pressure as a function of school noise level and the number of years enrolled in school following T1.

classroom children, whose means on these questions were nearly identical. The multivariate analysis for the child questionnaire data did not indicate any significant effects.

Health. The health cluster analyses indicated Noise \times Months Enrolled in School interactions for both height, $F(2, 237) = 2.83$, $p < .06$, and weight, $F(2, 237) = 4.21$, $p < .01$. These interactions were primarily attributable to relatively low mean heights and weights for those in the abated group who had been enrolled in their schools between 2 and 3½ years. There was also a main effect of noise for the percentage of total school days a child was in attendance, with noisy- and abated-group children attending more often (97.5% for noise and 97.2% for abated) than quiet-group children (94.2%), $F(2, 237) = 11.93$, $p < .0001$. Multivariate analyses for both the noise, $F(6, 470) = 1.58$, $p < .15$, and Noise \times Months, $F(6, 470) = 1.85$, $p < .09$, effects were marginal.

Blood pressure. As is apparent from Table 2, both systolic and diastolic blood pressures appear to vary as a function of noise level, with the highest mean pressure reported for the noise group, followed by a lower blood pressure in the abated group and an even lower pressure in the quiet group. Although the analysis of systolic pressure did not indicate a statistically significant impact of noise, there was a main effect of noise for

Table 2
Mean Blood Pressures (mm Hg) by Classroom
Noise Abatement for Cross-Sectional (T1) Data

Blood pressure	Classroom		
	Quiet	Abated	Noisy
Systolic	86.64	88.69	90.09
Diastolic	44.99	46.77	48.46

diastolic pressure, $F(2, 241) = 3.19, p < .04$. The multivariate analysis was not significant.

Preplanned contrasts between the various blood pressure means indicate that for both systolic, $F(1, 235) = 2.61, p < .10$, and diastolic pressure, $F(1, 235) = 5.24, p < .02$, the noise group was different from the quiet group. Comparisons between the quiet group and the abated group indicated marginal differences in both cases—for systolic, $F(1, 235) = 2.21, p < .14$; for diastolic, $F(1, 235) = 3.17, p < .08$. There were no differences between the noise and abated groups for either systolic or diastolic pressure.

Helplessness. The percentage of failure on the second helplessness puzzle was also consistent with the expected order. The noise group was more likely to fail the second helplessness puzzle (57% failed) than either the abated group (47% failed) or the quiet group (35% failed), $F(2, 235) = 4.12, p < .02$. There was no difference between noise groups on the time required to solve the second puzzle. Preplanned contrasts comparing proportions of students solving the second puzzle indicate marginal differences between the quiet and abated groups, $F(1, 235) = 3.10, p < .08$, and the noise and abated groups, $F(1, 235) = 2.70, p < .10$, and a significant difference between noise and quiet, $F(1, 235) = 8.03, p < .005$. These data suggest that noise abatement marginally affected puzzle task performance, with children in abated classrooms performing at a higher level than those in nonabated rooms, but not as well as those in quiet rooms.

Both the noise and the abated group "gave up" on the second puzzle (17% for noise, 16% for abated) more often than the quiet group (3%). The multivariate effect for noise did not, however, reach statistical significance. An analysis including only those children who failed the second puzzle indicated

that the failures of noise- (29%) and abatement-group (35%) children were associated with giving up more often than were the failures of quiet-group children (7% who failed gave up).

School achievement. The achievement tests for reading and math are administered by the school systems during the third but not during the fourth grade. As a result, the scores that were used in the following analyses were recent for third graders (administered at approximately the same time as our own testing) but were 1 year old for fourth graders. Thus, it was expected that noise abatement would affect the achievement scores of third graders who spent a year in their abated classrooms before (and while) taking the test, but not fourth graders, since their classroom assignment at the time that we collected our data was presumably irrelevant to how they performed on a test taken in another classroom 1 year earlier. (Unfortunately, data on the classroom assignment of fourth graders during the year that they were tested were not available.) To test the hypothesis that the achievement scores of third but not fourth graders would be affected by abatement, a Grade \times Noise interaction was added to the noise nested in classrooms analysis of the school achievement cluster. Although there were no effects for the noise or Noise \times Grade interaction on either reading achievement or auditory discrimination, there was a Grade \times Noise interaction for performance on the math achievement test, $F(2, 32) = 3.06, p < .06$; the multivariate for noise was $F(6, 60) = 1.98, p < .08$. As is apparent from Table 3, although grade level did not have a substantial effect on the relative performance of third and fourth graders in quiet schools,

Table 3
Mean (Adjusted) School Achievement
Percentiles for Cross-Sectional (T1) Data as a
Function of Classroom Noise Abatement and
Grade

Classroom	Reading		Math	
	3rd grade	4th grade	3rd grade	4th grade
Noisy	30.30	35.96	34.35	39.35
Abated	47.36	37.90	56.24	37.54
Quiet	37.85	39.09	36.96	42.76

third graders in abated classrooms performed substantially better than those in nonabated classrooms, whereas the reverse was true for fourth graders. It is also apparent from Table 3 that there was a similar pattern for reading test scores, although the Grade \times Noise interaction for reading did not reach statistical significance.

One anomaly of these data is that math (also reading) achievement performance of the third-grade children from abated classrooms in noisy schools is higher than that of third-grade children from quiet schools. It was noted in a previous article (Cohen et al., 1980) that differences between noisy and quiet schools were affected by a number of variables that could not be controlled for in the present study, including school and district teaching policy, teaching quality, level of federal aid to a school, and school administration. It was also suggested that these factors are probably more important than noise in determining school achievement. These problems are reduced substantially when (as in the analysis above) the noise and abated classrooms are in the same district and often in the same school.

Distraction. Analysis of the distraction task data indicated no significant effects.

Results: Longitudinal Analyses

As mentioned earlier, all children from the original sample who were still enrolled in their respective schools were retested 1 year later. The analyses presented below compare those children who were in noisy (non-abated) classrooms during both testings (44 children) with those children who were in noisy rooms during the first testing and abated rooms during the second testing (39 children). Quiet-classroom children were not included in these analyses because of the conceptual problem of evaluating change scores when initial scores are significantly different (see Table 1, V). Only factors for which Noise \times Testing Session and/or Noise \times Months \times Testing Session interactions were significant will be discussed, since at this point we are not concerned with differences between noise/noise and noise/abated groups that occur at both testings (i.e., the main effect for noise) unless an interaction is found.

Noise measures. Before presenting data

Table 4
Mean Classroom Noise Levels for Noisy and Abated-Noise Classrooms at T2

Noise level	Noise measure		
	L_{EQ}	L_{33}	Peak dB (A) ^a
Noisy	70.29	55.82	91.50
Abated	62.82	49.27	71.27

^a Mean peak dB (A) measures at T2 are higher than those recorded at T1. This is because the more sensitive automated equipment used at T2 records peaks that last only a fraction of a second, whereas manual equipment used at T1 required the operator to judge the highest point reached by a fluctuating needle.

on the relationship between the noise-abatement work and the children's performance and health, it is important to determine whether the abatement work was effective. Analyses of the differences in the sound levels in classrooms that were sound attenuated versus those that were not sound attenuated suggests that the abatement work had a significant impact on interior sound levels. As apparent from Table 4, on all three measures— L_{EQ} : $F(1, 20) = 9.39, p < .006$; L_{33} : $F(1, 20) = 4.92, p < .04$; and peak dB: $F(1, 20) = 24.91, p < .0001$ —abated rooms have substantially lower sound levels than non-abated rooms.

Child questionnaire. Children in the noisy group reported more trouble hearing their teacher during the second testing session, whereas those in abated classrooms reported less difficulty—Noise \times Testing Session, $F(1, 48) = 3.98, p < .05$. There were no other Noise \times Testing Session effects on children's questions and no significant multivariate effects.

There were no significant multivariate or univariate interactions of noise and testing session in any of the remaining clusters; thus, no additional data are reported here. It is important to reiterate that school achievement data were available only at T1, and thus, there were no longitudinal school achievement analyses.

Discussion

The cross-sectional comparison of noisy, abated, and quiet classrooms suggests only a minimal impact of the abatement intervention on the criterion variables. Clusters

apparently *unaffected* by abatement (those showing no effects or just noisy-versus quiet-school differences) include children's perceptions of noise and noise interference, health factors, and the auditory distraction measure. On the other hand, two important clusters did provide at least marginal support for an ameliorative effect of abatement. First, abatement did have a marginal effect on whether the child was able to solve the moderately difficult test puzzle in the helplessness task, irrespective of whether the child received a soluble or insoluble first puzzle. It is noteworthy, however, that giving up—the measure designed to provide a direct assessment of feelings of helplessness—was affected only by the noisy-school versus quiet-school distinction. Second, although reading achievement and auditory discrimination ability were unaffected by abatement, there was evidence that math achievement was higher for children in abated than in noisy classrooms. This effect seems especially noteworthy, since it occurs, as predicted, only for those children who took the achievement test at the end of the year that was spent in an abated classroom. It is important to consider, however, that unlike all other measures that were administered in a relatively quiet setting, the achievement tests were actually taken in the classroom. Thus, the relative deficit in math performance of the children from the noisy as opposed to noise-abated classrooms may be attributable to noise interfering with test performance rather than to an aftereffect of noise, which we would expect to occur even outside of the noise-impacted environment.

The *longitudinal* data similarly provide little evidence that children who had been enrolled in a noise-impacted school showed improvement in their performance and/or health following a 1- (school) year experience in a noise-abated classroom. In contrast to the cross-sectional analysis, the longitudinal data did not even indicate improvement in ability to solve the moderately difficult puzzle on the part of children in noise-abated rooms. This failure to mimic the cross-sectional findings may be due to an attrition bias or to the marginality of the effect itself. Unfortunately, school achievement data were not available during the second testing session, and there was no opportunity to reevaluate the ameliorative effects

of noise abatement on school achievement found in the cross-sectional analyses.

It is clear that the ameliorative effects of classroom noise abatement were not substantial, nor did they cover a wide range of measures. There is evidence, however, that abatement affects behavior in the classroom. Children in abated classrooms reported fewer problems hearing their teachers and performed better on school achievement tests than children in nonabated rooms. It is important to reiterate that unlike other measures in the study, school achievement tests were administered in the (noisy or quiet) classroom. It is thus possible that noise-associated deficits on this measure reflect an effect of noise that occurs *during* rather than after exposure.

We can suggest two possible explanations for the general lack of ameliorative effects of classroom noise abatement. First, it is possible that effects of previous noise exposure are relatively long lasting. That is, it takes more than a 1-year reprieve from the noise for a return to more normal levels of behavior and health. Second, since the children are all exposed to the noise outside of the school—in their homes, on the playground, and so forth—a quieter classroom may not have been a sufficient intervention.

In evaluating these results, it is also important to remember that most of the children attending noisy schools spent previous years in nonabated classrooms. Thus, although abatement interventions were not entirely effective for this population, it is possible that children who start to attend school after the entire school has undergone noise abatement (and are thus always in relatively quiet classrooms) would benefit from the interventions.

Conclusions and Implications

The data reported in the analyses of the entire T1 sample (Cohen et al., 1980) indicated effects of aircraft noise on cognitive, motivational, and physiological mechanisms that were consistent with effects found in laboratory settings. The data presented in this article established the stability of these effects over time. Moreover, they reinforce our interpretation of the earlier cross-sectional data that children do *not* adapt to noise over time. The analyses of noise-abate-

ment effectiveness indicate that the abatement is partially effective, with the important school achievement measure showing some improvement for children in noise-abated classrooms.

From a policy point of view, these data support the need for noise-abatement work in these kinds of settings but suggest that noise insulation in the classroom may not be enough. It is likely that more effective noise abatement in classrooms (bringing levels closer to those in quiet schools) and decreased noise exposure *outside of school* would have an increased ameliorative impact. Thus, decreasing overall community noise levels by creating buffer zones between airports and other sources of high-intensity noise and the surrounding communities would be one way of providing more adequate protection for community residents.

The data reported in this and the previous article are part of the Los Angeles Noise Project, an ongoing study that is attempting to provide a sound data base regarding the possible links between community noise exposure and various aspects of behavior and health. The consistency of laboratory and field findings is beginning to increase our confidence in a number of deleterious effects of community noise exposure. This project includes an ongoing attempt to replicate this work, with both a second sample of children living in the air corridor and a sample of children attending schools adjacent to highways. The aim is to increase our understanding of the aftereffects of noise, the possible role of adaptation in mediating such effects, and the impact of noise-abatement intervention on noise-related effects. The strategy of studying effects that are closely linked to laboratory findings together with the use of both cross-sectional and longitudinal approaches in the field helps establish both the scientific validity and practical value of work, with implications for social issues. As these converging approaches eliminate alternative explanations for noise-associated effects, the potential for affecting the formation of public policy increases.

Physiological, Motivational, and Cognitive Effects of Aircraft Noise on Children

Moving From the Laboratory to the Field

SHELDON COHEN *University of Oregon*

ABSTRACT: *A combination of laboratory and field methodologies is suggested as a strategy to increase the influence of psychological research in the formation of public policy. A naturalistic study of the effects of aircraft noise on elementary school children is presented as evidence for the effects of community noise on behavior and as an example of a study that examines the generality of laboratory effects in a naturalistic setting. The study is concerned with the impact of noise on attentional strategies, feelings of personal control, and physiological processes related to health. In general, the results are consistent with laboratory work on physiological response to noise and on uncontrollable noise as a factor in helplessness. Thus children from noisy schools have higher blood pressure than those from matched control (quiet) schools. Noise-school children are also more likely to fail on a cognitive task and are more likely to give up before the time to complete the task has elapsed. The development of attentional strategies predicted from laboratory and previous field research was, on the whole, not found. The implications of the study both for the understanding of the relationship between noise and behavior and for the influencing of public policy are discussed.*

Science's contribution to social policy decisions regarding noise pollution has been primarily limited to the documentation of the impact of high-intensity sound on hearing. Acceptable noise standards used in both national and local statutes are based on research that assesses magnitude of hearing loss at varying intensities and durations of sound. Yet during the last ten years it has become clear that noise can alter nonauditory systems as well as auditory ones. Thus laboratory research has established effects of noise on cognitive, motivational, and general physiological pro-

cesses. For example, noise is associated with alterations in task performance (cf. Broadbent, 1978; Loeb, 1979), decreased sensitivity to others (e.g., S. Cohen & Lezak, 1977; Mathews & Canon, 1975), and elevation of a number of nonspecific physiological responses (cf. Glass & Singer, 1972; Kryter, 1970). Exposure to noise that is unpredictable and uncontrollable (cannot be escaped or avoided) can also reduce one's perception of control over the environment (e.g., Glass & Singer, 1972; Krantz, Glass, & Snyder, 1974). This loss of control is often accompanied by a depression of mood and a decrease in one's motivation to initiate new responses (Seligman, 1975).

One argument against serious consideration of this evidence when making policy decisions is that it is largely derived from laboratory studies. Since laboratory subjects typically experience a single short period of exposure to high-intensity sound and are aware that their exposure is only temporary, the applicability of these findings to experi-

The research reported in this article was supported by grants from the National Science Foundation (BNS 77-08576 and SOC 75-09224), the National Institute of Environmental Health Sciences (1 RO1 ES0176401 DBR), the Society for the Psychological Study of Social Issues, and the University of Oregon Biomedical Fund.

ences of chronic noise exposure is questionable. Because of a lack of well-controlled studies of persons routinely living and working under noise, we are unable to say with any certainty if similar effects occur in individuals exposed to noise for prolonged periods.

Our own lack of confidence in the generality of the effects of noise that occurs in laboratory settings translates into a lack of influence in the policy-making process. Legislation restricting noise levels in industrial and community settings usually imposes a heavy economic burden on those responsible for the noise. To convince policymakers that such burdens are justified, there must be substantive evidence that community and/or industrial noise deleteriously affects health and behavior.

Naturalistic studies of the effects of noise that occurs in home, school, or office seem like the obvious alternative to investigations carried out in laboratory settings. However, such studies are correlational. Subjects are not randomly assigned to noisy or quiet settings, and the settings often vary on dimensions other than noise exposure. These problems can be substantially reduced by carefully matching the noise and quiet samples on important dimensions and by statistically controlling for other possible confounds. It is always possible, however, that some unknown factor covaries with exposure to the noise setting and actually causes the effects that the investigator associates with noise. Thus, in isolation, naturalistic studies also provide insufficient evidence for a link between community noise and measures of health and behavior.

It is clear that neither laboratory nor naturalistic studies can in themselves provide what either scientists or politicians would consider convincing evidence for noise-induced effects. What is necessary is an interplay between laboratory and field methodologies. This interplay can take at least two forms. On the one hand, an effect can first be established as reliable within laboratory settings where causal links can be inferred. Then, the robustness of this relationship can be established in a number of naturalistic settings. On the other hand, by first conducting field research, it is possible to isolate important dimensions of a particular problem. At that point, laboratory studies may be useful to rule out plausible alternate explanations often inherent in naturalistic research. Laboratory and field approaches are often pursued to the exclusion of one another, but only by com-

binning these two strategies can we begin to understand the impact of environmental variables in naturalistic settings. Moreover, only when evidence from the laboratory and field converges can a credible scientific case be presented in order to influence public policy.

This emphasis on the interplay between the laboratory and the field is consistent with Campbell and Stanley's (1966) discussion of the inevitable trade-off between well-controlled experimental settings (internal validity) and our ability to generalize across persons and settings (external validity). The laboratory provides the opportunity for an internally valid investigation, but the generality of laboratory findings is severely restricted. Naturalistic studies provide the opportunity to generalize findings to a greater range of persons and settings but often lack the strict control of the laboratory.

The study presented in this article examines the effects of aircraft noise on children. It is particularly concerned with exploring the generality of laboratory work on noise-induced shifts in attentional strategies, feelings of personal control, and nonauditory physiological responses related to health. Our purpose in reporting this study is twofold. First, it is presented as evidence for relationships (or lack of relationships) between aircraft noise exposure and a number of cognitive, motivational, and physiological measures. The article includes short discussions of laboratory and field research in each of the areas of concern. Second, it is presented as an example of an attempt to examine the generality of laboratory effects in a naturalistic setting. In this regard, the study employs an individual testing procedure in a field setting. It uses a matched-group design and attempts to control statistically for a number of possible alternative explanations for correlations between community noise and the various criterion variables.

Overview of the Study

The subjects were children attending the four noisiest elementary schools in the air corridor of Los Angeles International Airport. Peak sound level readings in these schools are as high as 95 dB (A), and the schools are located in an air corridor that has over 300 overflights a day—approximately one flight every 2.5 minutes during school hours (Lane & Meecham, 1974). Three control

schools (quiet schools) were matched with the experimental schools for grade level, for ethnic and racial distribution of children, for percentage of children whose families were receiving assistance under the Aid to Families with Dependent Children program, and for the occupations and education levels of parents. Thus we were able to compare samples of children attending noise schools and quiet schools who were relatively similar in terms of age, social class, and race. A statistical technique described later allowed additional control over these factors.

The study focused on effects occurring outside of noise exposure (i.e., aftereffects). Thus all tasks and questionnaires (except the achievement test records gathered from school files) were administered in a quiet setting—a noise-insulated trailer parked directly outside the school. These data were collected during two 45-minute sessions on consecutive days. Three cognitive tasks were administered during the test periods. One was designed to assess feelings of personal control and the others to determine whether the children employed some common attentional coping strategies. A questionnaire concerned with responses to noise and two blood pressure measures were also given during the testing sessions. A parent questionnaire dealing with parent response to noise, mother's and father's level of education, and the number of children in the family was sent home with each child. Scores on standardized reading and math tests and data on absenteeism were collected from school files.

The study included children from all noise-impacted third- and fourth-grade classrooms in each noise school as well as children from an equal number of classrooms in quiet schools. To ensure that performance differences between children from noise schools and those from quiet schools could not be attributed to noise-induced losses in hearing sensitivity, an audiometric pure-tone threshold screening was administered to each child. Children were screened at 25 dB for select speech frequencies (500, 1000, 2000, and 4000 Hz). Children failing to detect 25 dB tones at any one of these frequencies in either ear were not included in the study. Six percent of the noise-school children and 7 percent of the quiet-school children failed the screening. A total of 262 subjects (142 from noise schools and 120 from quiet schools) remained in the study. Individual analyses, how-

ever, sometimes contain fewer subjects because of missing data.

Data compiled from the parent questionnaire allowed us to determine the degree of similarity of the prematched noise and quiet samples. Analyses of variance indicated that there were no differences between the samples on the various social class factors. The mean number of children per family was 3.54 in the noise sample and 3.88 in the quiet sample. Levels of parent education were also equivalent, falling between some high school (scaled as 3) and high school graduate (scaled as 4). The mean level of education for fathers was 3.75 for noise-school children and 3.41 for quiet-school children, and for mothers, 3.64 and 3.35, respectively. The racial distributions, however, differed significantly, $\chi^2(3) = 10.5$, $p < .01$, with the noise group containing more blacks (32% vs. 18%) and the quiet group more Chicanos (50% vs. 33%). Noise and quiet samples had nearly equal percentages of whites (32% and 29%, respectively) and of unidentifiable or mixed-race children (3% in each sample).

The two samples also differed on mobility, with children in the quiet sample having lived in their homes longer (a mean of 49.6 months vs. 41.4 months) and attended their schools for longer periods (a mean of 43.2 months vs. 36.0 months) than noise children, $F(1, 270) = 4.8$, $p < .03$, and $F(1, 270) = 12.9$, $p < .001$, respectively. Length of school enrollment was not related to father's education, mother's education, or the number of children in the family. Moreover, the noise and quiet samples were relatively equal on these various social class factors across all durations of exposure. This finding suggests that the decision to continue living in the noise-impacted area was not determined by the parents' socioeconomic status. There were, however, more blacks and whites in the noise group with less than 2 years' exposure than there were in the equivalent quiet group, $\chi^2(4) = 12.04$, $p < .02$. There were no differences in racial distribution for other exposure durations.

Statistical Controls

A regression technique was used to compensate for differences between the noise and quiet samples on racial distribution and mobility (J. Cohen, 1968). In general, the regression analysis allows one to determine the relation between two variables while

ing evidence for noise-induced physical disease (cf. S. Cohen, Glass, & Phillips, 1979; Kryter, 1970). It is well established, however, that short-term exposure to relatively high sound levels in laboratory settings can alter physiological processes. Physiological changes produced by noise consist of non-specific responses typically associated with stress reactions, including increases in electrodermal activity, catecholamine secretions, vasoconstriction of peripheral blood vessels, and diastolic and systolic blood pressure. Because such changes, if extreme, are often considered potentially hazardous to health, many feel that pathogenic effects of prolonged noise exposure are likely. Laboratory evidence that some components of the physiological response to noise do not habituate (Jahsen, 1969) lends fuel to this argument, but is difficult to interpret in light of evidence from other laboratories indicating complete habituation (Glass & Singer, 1972).

A number of studies of workers in noisy industries have indicated health problems for those exposed to intense noise levels. Included are respiratory problems, such as sore throat, and allergenic, musculoskeletal, circulatory, neurological, cardiovascular, and digestive disorders (e.g., Anticaglia & Cohen, 1974; A. Cohen, 1973). However, all of the industrial noise studies are subject to serious criticism because of their failure to control for other adverse workplace or job factors, for example, task demands and risks, that often covary with the noisiness of the job (cf. S. Cohen et al., 1979; Kryter, 1970). It is also important to note that several industrial surveys have failed to find a relation between noise and ill health (e.g., Finkle & Poppen, 1948; Glorig, 1971).

There are no existing controlled studies on the impact of noise on nonauditory health in children (Mills, 1975). Recent theoretical work, however, argues that children (along with the old, individuals in institutions, and persons suffering from other sources of stress) may be particularly susceptible to noise-induced illness because they lack the ability to temporarily escape their noisy environments (S. Cohen et al., 1979). It is suggested that this inability to escape at will can cause both an increase in overall duration of noise exposure and an increase in feelings of helplessness. This effect is important, since feelings of helplessness have been implicated as possible causal factors in illness (Seligman, 1975).

Each child's resting blood pressure (systolic and diastolic) was taken on an SR-2 Physiometrics automated blood pressure recorder.³ To acustom the children to the blood pressure measurement technique, an initial measurement was made at the beginning of the first day of testing. A short explanation of the technique and the concept of blood pressure was given at this time, and questions were solicited and answered. This initial measurement was not recorded. Each child's blood pressure was measured again on the first day and once more on the second day. The blood pressure data are based on the mean systolic and diastolic pressures for these two measurements. The graphic output of the machine was coded after the study was completed, with coders blind to experimental condition. Each child's height and weight were also measured. Absenteeism was used as an indirect measure of health, since absence from school is often attributable to illness. These data were available from school files.

Health measures were separated into two multivariate clusters: general health measures and blood pressure. This procedure was necessary because two of the general health measures—height and ponderosity (weight/height³)—were required as controls for the blood pressure analyses (cf. Voors et al., 1976). (The ponderosity index was chosen as a measure of obesity because of its high correlation with body fat.) The multivariate F for the effects of noise on the general health cluster was significant, $F(3, 235) = 8.04, p < .001$. Although noise-school children were shorter and weighed less than quiet-school children, neither of these differences reached significance, $F(1, 237) = 1.77, p < .18$, and $F(1, 237) = 1.07, p < .30$, respectively. Surprisingly, noise-school children attended school a higher percentage of the time (97.5% vs. 94.2%) than their quiet-school counterparts did, $F(1, 237) = 21.80, p < .001$.

The multivariate F for the effects of noise on systolic and diastolic blood pressure was significant, $F(2, 244) = 2.98, p < .05$. As is apparent from Figure 1, children from noise schools had higher blood pressure than their quiet-school counterparts did, with $F(1, 245) = 4.61, p < .03$, for

³ This instrument is an electronic infrasonic device that records on a rotating paper disc. Measurements were taken with a rubber cuff entirely encircling the upper arm. The reliability of this device for blood pressure measurement in children has been established in previous work (e.g., Voors, Foster, Frerichs, Weber, & Berenson, 1976).

controlling (covarying or partialing out) for one or more other variables. For example, one can look at the relation between noise level and blood pressure after functionally equating the noise and quiet groups on mobility and race. All data analyses reported in this article include controls for the number of children in the child's family, the grade in school, the number of months enrolled in school (years in residence for the parent questionnaire), and race.¹ These control factors were forced into the regression first, followed by noise and then the Noise \times Months Enrolled in School interaction. The interaction indicates whether length of exposure affected the various criterion measures. Additional controls were used in the analyses of blood pressure, school achievement, and selective inattention. The use of these controls is described in appropriate sections. This conservative analysis looks at the effects of noise and the interaction between noise and length of enrollment after functionally equating the noise and quiet groups on grade, race, social class, and mobility, as well as on any additional control factors employed in a particular analysis.

The various measures were analyzed in predetermined multivariate clusters created on the basis of theoretical consideration.² This form of analysis helps to decrease the high probability of chance findings that occur when a large number of analyses are necessary (cf. Bock, 1975).

Noise Measures

Interior sound levels (without children) were measured inside each classroom with Tracoustics (SLM S2A) sound level meters. Sound levels were monitored for a 1-hour period in the morning and a 1-hour period in the afternoon. Peak sound levels in terms of dB (A) were recorded for both morning and afternoon sessions. The overall mean peak for classrooms in noise schools was 74 dB and in quiet schools 56 dB. The highest reading in a noise-school classroom was 95 dB, while the highest reading in a quiet school was 68 dB.

The questionnaire administered to each child assessed his or her perception of classroom and home noise levels. The parent questionnaire also included questions on perception of home noise level as well as queries on how long the child had been enrolled in the present school and how long he or she had lived at their present address. Data on school enrollment were also available from school files. Noise contours (compiled by the Los

Angeles International Airport) provided approximations of the sound levels outside the homes of noise-school children.

The multivariate F for the effects of noise on the children's noise questionnaire was significant, $F(9, 246) = 3.10, p < .002$, thus allowing interpretation of the univariate regressions. Children in noise schools reported that their classrooms were noisier, $F(1, 254) = 5.49, p < .02$, and that airplanes bothered them more in the classroom, $F(1, 254) = 14.74, p < .001$, than children in quiet schools did. They did not, however, report having more trouble hearing their teacher.

In regard to home noise, children from air-corridor schools were more bothered by airplane noise than their quiet-school counterparts were, $F(1, 254) = 15.75, p < .001$. However, noise- and quiet-school children did not differ in ratings of home noise. Neither the multivariate F nor any univariate regression indicated any significant effects for the Noise \times Months in School interaction on the children's questionnaire.

The multivariate F for the effects of noise on the parents' noise questionnaire was also significant, $F(2, 221) = 124.2, p < .001$. Parents of children from the air-corridor schools indicated both that there were higher levels of noise in the home, $F(1, 232) = 37.33, p < .001$, and that they were bothered more by noise, $F(1, 232) = 240.07, p < .001$, than the parents of children attending quiet schools indicated. The home noise level reported by the parents of noise-school children increased with the number of years they had lived in their present residence, $F(1, 220) = 3.11, p < .08$. This effect must be interpreted carefully, however, since both the univariate and multivariate F s were only marginally significant.

Effects of Noise

PHYSIOLOGICAL RESPONSE AND HEALTH

Aside from temporary and permanent effects on hearing, previous research provides little convinc-

¹ Parent education was excluded as a control because data on this factor were not available for a number of children. As mentioned earlier, the noise and quiet samples were closely matched on education. Race was dummy-variable coded (see Overall & Klett, 1972).

² There were separate clusters for general health, blood pressure, helplessness, child questionnaire, and parent questionnaire. The selective inattention analyses were run as univariates, since each analysis required a unique control factor.

systolic pressure and $F(1, 245) = 4.86, p < .03$, for diastolic pressure.⁴ Unadjusted means for systolic pressure were 89.68 mm for the noise group and 86.77 mm for the quiet group. Diastolic means were 47.84 mm for the noise group and 45.16 mm for the quiet group. A marginal interaction, $F(1, 244) = 3.30, p < .07$, between noise and months in school suggests that systolic pressure differences between noise and quiet groups are greatest during the first few years of school enrollment; differences after this point remain constant. Figure 1 reflects a similar pattern for diastolic pressure. This interaction does not, however, reach even marginal statistical significance.⁵

HELPLESSNESS

Both laboratory and community noise research suggests the possibility that high-intensity noise exposure induces feelings of helplessness. According to Seligman (1975), a psychological state of helplessness frequently results when we continually encounter events (especially aversive ones) that we can do nothing about. The state of helplessness includes a perception of lessened control over

one's outcomes, a depression of mood, and a decrease in one's motivation to initiate new responses. Extreme effects of helplessness include fear, anxiety, depression, disease, and even death.

A number of researchers have induced helplessness effects in the laboratory by exposing subjects to uncontrollable bursts of noise (Hiroto, 1974; Krantz et al., 1974). Moreover, survey data reporting high levels of annoyance but low levels of complaints from noise-impacted populations have similarly been interpreted as reflecting a helplessness-like state (Herridge, 1974). This finding, however, is subject to a number of alternative explanations, and thus the helplessness interpretation is only suggestive.

Performance on a cognitive task preceded by a success or failure experience was used in the present study to examine the effect of noise on response to failure and on persistence on a difficult task. Response to failure is a standard measure of susceptibility to helplessness. Thus, if noise-school children were more susceptible to helplessness, they would show greater effects of a failure experience than their quiet-school counterparts would. A lack of persistence (or a "giving-up" syndrome) is considered a direct manifestation of the helpless state.

Each child was given a treatment puzzle to assemble after the tester demonstrated the task with another puzzle. All puzzles were based on the same nine pieces and required the child to fill in a template of a familiar shape. One half of the

Figure 1. Systolic and diastolic blood pressure as a function of school noise level and duration of exposure. (Each period on the years-exposure coordinate on the figure represents approximately one quarter of the sample. For example, 25% of the sample had been enrolled in the present school less than 2 years.)

⁴ Both the noise-school and quiet-school children have lower mean blood pressures than children of similar ages tested in recent studies (e.g., Voors et al., 1976). It is important to note, however, that it is difficult to compare absolute blood pressure levels across studies, since blood pressure is strongly influenced by environmental and genetic characteristics of the population being studied, the conditions under which measurement occurs, and the measurement device.

⁵ To investigate whether elevations in blood pressure occurred equally across races, separate regressions were calculated for whites, blacks, and Chicanos. Since the number of subjects in each of these regressions is small, only very substantial mean differences will reach statistically significant levels. Blacks and Chicanos attending noise schools had higher systolic ($p < .05$ for blacks, $p < .25$ for Chicanos) and diastolic ($p < .25$ for blacks, $p < .10$ for Chicanos) pressure than their quiet-school counterparts did. For whites, there were no main effects of noise, but an interaction between noise and length of school enrollment indicated that an initial inflation of pressure for noise-school children disappeared as length of enrollment increased ($p < .01$ for both systolic and diastolic). These race differences will be pursued in a later paper.

children received an insoluble (failure) puzzle, and one-half received a soluble (success) puzzle. The soluble puzzle was a circle, and the insoluble puzzle was a triangle. Each child was allowed to work on the treatment puzzle for 2.5 minutes. After time was up on the first puzzle, the child was given a second, moderately difficult puzzle to solve. The second (test) puzzle was the same—a square—for all (success and failure) children. The child was allowed 4 minutes to solve the second puzzle. Whether or not the puzzle was solved, time to solution and the child's persisting or giving up before the 4 minutes had elapsed were used as measures of helplessness. We expected that children from noisy schools would be more susceptible to a failure (helplessness) manipulation than children from quiet schools would be, and thus would be less likely to solve the puzzle, slower to find the solution, and more likely to give up on the second puzzle following an insoluble (failure) treatment. Moreover, children from noisy schools, irrespective of their success-failure condition, were expected to give up more often than quiet-school children.

A large proportion (34%) of the children assigned to the success condition, and thus receiving a soluble treatment puzzle, failed to solve the treatment puzzle within the 2.5 minutes allowed. Since the puzzles were considered quite simple and had been pilot tested on children of the same age group, this result was quite unexpected. Although the fact that a number of children self-selected themselves into a failure condition makes interpretation of success-failure effects impossible, comparisons between the children from noise schools and those from quiet schools, irrespective of (controlling for) their pretreatment, are still valid.

Except for the first analysis, which includes only those children who worked on soluble treatment puzzles (success condition), the following analyses also include factors for success-failure (those who solved and those who did not solve the success treatment puzzle are treated as separate groups) and the interaction between success-failure and noise. The control factors were forced into the regression first, followed by success-failure (dummy coded), noise, and the Noise \times Success and Noise \times Months Enrolled interactions. Because of the difficulty in interpreting success-failure effects, they are not discussed. Moreover, since there were no significant interactions between

Figure 2. Performance on the second (test) puzzle as a function of school noise level and duration of exposure. (Each period on the years-exposure coordinate on the figure represents approximately one quarter of the sample. For example, 25% of the sample had been enrolled in the present school less than 2 years.)

success-failure and school noise level, the reported results are limited to the overall effects of noise.

First, an examination of only those who were assigned to the success treatment condition indicates that children from noise schools were more likely to fail to solve the treatment puzzle (41% failed) than children from quiet schools were (23% failed). This effect, however, was only marginally significant, $F(1, 131) = 3.62, p < .07$. Second, there were similar effects of noise on the second puzzle, which occurred irrespective of whether the child received a success (solved or not) or failure treatment. As was the case with the first puzzle, noise-school children were more likely to fail the second puzzle (53% failed) than quiet-school children were (36% failed), $F(1, 246) = 5.99, p < .09$, and were more likely to give up, $F(1, 246) = 11.15, p < .001$, than their quiet-school counterparts were, multivariate $F(3, 244) = 4.59, p < .004$. As is apparent from Figure 2, a marginal interaction between noise and months enrolled in school, $F(1, 243) = 3.27, p < .07$, suggests that the longer a child had attended a noise school, the slower he or she was in solving the puzzle. However, the multivariate F for this interaction was not significant.

Although the preceding analyses indicate that children from noise schools are generally less capable of performing a cognitive task (at least puzzle solving) than children from quiet schools are, they provide only suggestive evidence that noise-school children feel or act as if they have less control over their outcomes. The strongest hint that failure on these puzzles on the part of noise-school children is related to helplessness is found in the data indicating that noise-school children were more likely to give up before their allotted time had elapsed than their quiet counterparts were. It is possible, however, that a constant proportion of children who failed on the second puzzle gave up. It would follow that the amount of giving up in the noise condition was inflated by the fact that there was a greater pool of failures. This interpretation suggests that increased giving up under the noise condition cannot necessarily be viewed as a sign of helplessness. A final analysis addresses this point. This analysis, which includes only those children who failed the second puzzle, indicates that the failures of noise-school children were associated with giving up (31% of those who failed gave up) more often than the failures of quiet-school children were (7% of those who failed gave up), $F(1, 103) = 5.85, p < .025$. Thus, even though all of these children failed to solve the puzzle, noise-school children were less likely to persist than their quiet-school counterparts were.

ATTENTIONAL PROCESSES DURING NOISE

Human performance studies report that noise often results in a restriction (or focusing) in one's breadth of attention (Broadbent, 1971; Hockey, 1970). Cues irrelevant to task performance are dropped out first, and then, if attention is further restricted, relevant task cues are eliminated. Performance improves under noise when discarded cues are those that are distracting or competing with primary task cues. Performance is adversely affected, however, when a task requires a wide breadth of attention and when focusing results in the neglect of relevant as well as irrelevant cues. Similarly, focusing can have a negative impact on interpersonal behavior when subtle social cues (e.g., another's look of distress) are dropped out, but can improve the quality of an interaction when the discarded cues are merely distracting (S. Cohen & Lezak, 1977).

There is suggestive evidence that an attentional focusing strategy will persist even after noise is terminated. A number of studies have shown post-noise effects on performance and interpersonal behavior (e.g., Donnerstein & Wilson, 1976; Glass & Singer, 1972). These aftereffects of noise are consistent with what one would expect to occur when one uses a focusing strategy (S. Cohen, 1978). As yet, however, there is no direct evidence that attentional focusing occurs following exposure to noise in either the laboratory or the field.*

Selective inattention. A strategy that is similar (and possibly identical) to attentional focusing has been proposed by Deutsch (1964) to account for the effect of community noise on the verbal abilities of children. Deutsch suggests that children reared in noisy environments become inattentive to acoustic cues. That is, they tune out their acoustic environment. (This could be viewed as their focusing their attention on other aspects of their environment.) Children who tune out their noisy environments are not likely to distinguish between speech-relevant and speech-irrelevant sounds. Thus, they lack experience with appropriate speech cues and generally show an inability to recognize relevant sounds and their referents. The inability to discriminate sound is presumed to account, in part, for subsequent problems in learning to read. Although recent research suggests that children living and attending school in noisy neighborhoods are poorer at making auditory discriminations and in reading (Bronzaft & McCarthy, 1975; S. Cohen, Glass, & Singer, 1973), there is no direct evidence for the selective inattention mechanism. An alternative explanation is that noise masks parent and teacher speech, similarly resulting in a lack of experience with appropriate speech cues and, as a consequence, in reading deficits.

The present study attempts to assess the relation between environmental noise level and the selective inattention strategy in order (a) to determine the generality of noise-induced shifts in attention that occur in laboratory settings and (b) to test Deutsch's (1964) hypothesis. In line with

* The only study on the impact of chronic noise exposure on attentional focusing resulted in rather ambiguous findings, with children from noisy homes (as reported by parents) exhibiting general performance deficits but no focusing strategy (Heft, 1979). A replication of the incidental memory task used in the Heft study was administered in the present study. Errors in administering the task, however, made the data uninterpretable.

the testing of the Deutsch hypothesis, the relation of the above-mentioned variables to auditory discrimination and reading achievement is also assessed.

Because children who are relatively inattentive to acoustic cues should be less affected by an auditory distractor, distractibility was used as a measure of selective inattention. Under both ambient and distracting conditions, the subjects performed a task consisting of crossing out the *e*'s in a two-page passage from a sixth-grade reader. They were instructed to move from left to right and from top to bottom of the page, as if they were reading, and to go as fast as they could without missing any *e*'s. Each subject worked on a short practice paragraph and then on the task for 2 minutes. Two versions (different samples of prose) were used.

In the distraction condition, the child worked on one of the versions of the task while a tape recording of a male voice read a story at a moderate volume. In the no-distraction condition, the alternative form of the task was completed under ambient sound conditions. The distraction and no-distraction tasks were administered on different testing days. Both the order of alternative versions of the task and the experimental conditions were counterbalanced. The criterion measure was performance (percentage of *e*'s found) on the distraction task after the scores were adjusted for no-distraction performance. It was expected that the children from noise schools would be less affected by distraction than the children from quiet schools. Since selective inattention is a strategy that develops over time, it was also predicted that this tuning-out strategy would increase with increased exposure (S. Cohen et al., 1973).

Separate analyses examined the number of lines completed under distraction and the percentage of *e*'s in the completed lines that were found under distraction. No-distraction performance (number of lines in the first analysis and percentage of *e*'s in the second) was added as an additional control variable in order to equate the children on their ability to perform the task under quiet conditions. There were no differences between the noise group and the quiet group (nor was there an interaction) on the number of lines completed under distraction. There was, however, a significant interaction between noise-quiet and months enrolled in school, $F(1, 237) = 5.05, p < .03$, for the percentage-of-*e*'s-found measure. As is apparent from Figure 3,

Figure 3. Distractibility as a function of school noise level and duration of exposure. (Each period on the years-exposure coordinate on the figure represents approximately one quarter of the sample. For example, 25% of the sample had been enrolled in the present school less than 2 years.)

the children in noise schools did better than the quiet group on the distraction task during the first 2 years of exposure and did worse after 4 years of exposure. Contrary to earlier evidence, this finding suggests that as the length of noise exposure increases, children are more, rather than less, disturbed by auditory distractors. One possible explanation for this effect is that at first, the children attempt (somewhat successfully) to cope with noise by tuning it out. Later, however, as they find that the strategy is not adequate, they give up. This interpretation is consistent with the helplessness data.

As suggested earlier, reading deficits in children from noisy neighborhoods have been attributed to noise-impacted children's selective filtering out of acoustic cues. Auditory discrimination and reading achievement were assessed in an attempt to replicate previous work and to determine whether there was an association between these measures and the children's attentional strategies. Standardized reading and math tests (administered during the second and third grades by the school system) were gathered from school files, and the Wepman Auditory Discrimination Test (Wepman, Note 1) was administered individually to children in the soundproof van. The Wepman test consists of 40 pairs of words, some of which differ from each other in either initial or final sound, for example,

sick-thick or *map-nap*. The pairs of words are recorded on tape and presented to each child through earphones. The child is instructed to report if the two words in each pair are the same or different. Control word pairs, in which the words are the same, allow for the elimination of children who have problems with same-different judgments or who are not attending to the task.

In order to roughly equate the noise and quiet conditions on the aptitude of the children at the time they entered school, the analyses of school achievement and auditory discrimination scores included an additional control for the mean cognitive abilities of the child's class on entering the first grade. None of the multivariate or univariate analyses were significant for this cluster. Math, reading, and auditory discrimination were all unrelated to both noise and the Noise \times Months Enrolled in School interaction.

Further analyses (Pearson correlations) suggest that the children who were better at auditory discriminations were also better on both the reading test, $r(231) = .19, p < .05$, and the math test, $r(231) = .18, p < .05$. There were, however, no significant relations between these variables and the selective inattention measure. The same analyses, including only noise-school children, and correlations partialing out control variables for both the entire sample and the noise sample yielded similar results. In summary, there is no evidence that aircraft noise affects reading and math skills, or that these skills are related to a selective inattention strategy.

Classroom as the unit of analysis. Since noise would be likely to have an impact on school achievement by affecting behavior in the classroom, a second analysis of the school achievement cluster was performed with classroom, rather than individual child, as the unit of analysis. This covariance analysis treated the control factors as covariates and months enrolled in school, noise, and classrooms (nested in noise) as independent variables. This analysis is considerably more conservative than the previous analysis because the degrees of freedom in the denominator are based on the number of classrooms (37) rather than on the number of children (262). The results for the school achievement cluster were the same.

The classroom analysis was not used for the other clusters, since those measures were not achievement oriented and thus were presumed not to be classroom mediated. The subjects were also

tested individually, not in the classroom. Even using this ultraconservative technique, however, a reanalysis of the other clusters indicates very similar results for the parent-questionnaire, blood pressure, and helplessness clusters. Differences between the noise group and the quiet group on the child-questionnaire and selective inattention clusters, which were significant in the previous analysis, did not reach statistical significance with classroom used as the unit of analysis.

QUIET HOMES AND NOISY SCHOOLS

To determine whether or not living in a relatively quiet home (at least in terms of aircraft noise) would lessen the impact of school noise, we isolated the children living in the 20 quietest homes in the noise sample, that is, in homes with contour levels of less than 68 in terms of the Community Noise Equivalency Level (CNEL).⁷ These children were then compared (using the regression techniques described earlier) with the remainder of the noise sample and with the entire quiet sample.⁸ In no case was there a difference between these quiet-home children and the remaining children of the noise sample. In a number of cases, however, even this small group of 20 showed the effects of noise reported earlier. Thus the noise-sample children from quiet homes were less likely to solve the first helplessness task puzzles than the quiet-sample controls were, $F(1, 132) = 3.04, p < .10$. The longer a child had attended a noisy school, the less likely he or she was to solve either the first puzzle, $F(1, 130) = 4.06, p < .05$, or the second puzzle, $F(1, 240) = 2.07, p < .15$. Moreover, children from quiet homes but noisy schools were more likely to fail, $F(1, 244) = 6.20, p < .01$, and to give up, $F(1, 244) = 11.95, p < .001$, on the second puzzle than children from quiet schools were, multivariate $F(3, 244) = 4.71, p < .003$. Further, their failures on the second puzzle were associated with giving up more often than the failures of quiet-school children were, $F(1, 102) = 6.27$,

⁷ CNEL is a measure of community noise giving more weight to noise occurring between 1900 and 2200 hours and the most weight to noise occurring between 2200 and 0700 hours (cf. Peterson & Gross, 1972).

⁸ Noise was dummy coded. The two contrasts discussed in this section were used to determine the impact of noise. This is a conservative technique of doing the contrasts, since the error term for the entire sample is used in calculating the F .

$p < .025$. Noise-school children from quiet homes also had both higher systolic blood pressure, $F(1, 240) = 3.59, p < .06$, and higher diastolic blood pressure, $F(1, 240) = 5.32, p < .02$, than children from quieter schools did, multivariate $F(2, 239) = 2.84, p < .06$. There were no effects, however, on the selective inattention task (crossing out *e*'s under distraction condition), as reported for the entire sample.

These analyses suggest that living in a relatively quiet neighborhood did not lessen the cumulative impact of exposure to noise at school. The reason may be that the noise experienced during school attendance is sufficient to create noise effects.

Air Pollution

A possible alternative explanation for differences between the noise and quiet samples is air pollution levels. Such an alternative is very unlikely. Sulfur dioxide was minimal at all the school sites, never exceeding the California standard (South Coast Air Quality Management District, Note 2; State of California, Note 3). Ozone and nitrogen dioxide standards were exceeded, but maximum levels were slightly higher at the control schools than at the airport schools. The maximum 1-hour rates in any school area for ozone (.21 parts per million) and NO_2 (.60 ppm) were below levels that generally show any effects on human behavior or health (Morrow, 1975; National Academy of Sciences, Note 4). Maximum carbon monoxide was slightly higher in the airport schools (30 vs. 27, 22 ppm), but average values were identical (6 ppm). The differences in maximum values of 8 ppm are negligible, and human effects from CO concentrations of less than 40 ppm are extremely rare (National Air Pollution Control Administration, 1970). Note that we have used maximum values in arguing against an air pollution alternative, thus presenting a very conservative counterargument. Average values in all cases were considerably below established standards.

Conclusions

In general, the evidence presented in this article is consistent with laboratory work on physiological response to noise and on uncontrollable noise as a factor in helplessness. Thus children from noisy schools have higher blood pressure and are more likely to give up on a task than children from

quiet schools are. The development of attentional strategies predicted from laboratory work and previous field research was, on the whole, not found. Contrary to prediction, increased years of exposure led to children's being more distractible rather than less. However, a general deficit in task performance on the puzzle task and increased distractibility do seem to support the more general hypothesis that prolonged noise exposure affects cognitive processes.

These data are most interesting, however, because of the tentative answers they provide concerning questions of adaptation to noise over time. One interpretation of the data is that they indicate some habituation of physiological stress response but show no signs of adaptation of cognitive and motivational effects. In fact, in a number of cases, increased length of exposure resulted in an increased negative impact of noise. First, the only evidence for an adaptation effect is provided by the systolic blood pressure data. On that measure, the greatest difference between the noise and quiet groups occurred during the first 2 years of exposure. As length of exposure increased, these differences leveled out but still remained substantial. Perceptions of noise and noise annoyance did not adapt. Thus children from noise schools and their parents reported more noise and being more bothered by noise. Parents, in fact, reported higher levels of noise as their length of residence in the noisy area increased. Neither the cognitive deficits on the helplessness puzzles (which actually increased over time) nor the giving-up syndrome of the children from noise schools lessened with increased length of exposure. Finally, although noise-school children were initially less affected by an auditory distractor, increased length of exposure (beyond 4 years) seemed to result in greater distractibility. Thus the preponderance of evidence suggests a lack of successful adaptation over time. The above interpretation, however, is only tentative. Although length-of-exposure differences may be due to increased exposure to noise, they may also be attributable to some unknown factors that differentiate between children who continue to live in the air corridor and those who move, or to some combination of exposure and these factors.

It should be noted that the failure of the present study to replicate the previously reported relation between community noise and reading ability (Bronzaft & McCarthy, 1975; S. Cohen et al.,

1973) may be attributable to an experimental design insensitive to noise-induced differences in school achievement. In both of the earlier studies, all the students attended the same school. Moreover, in the Cohen et al. study, students from both noisy and quiet apartments were taught in the same classrooms by the same teachers. In the present study, noise-sample children and quiet-sample children attended different schools, were in different classrooms, and had different teachers. It is likely that these factors add substantial error variance to the equation, making the detection of a small effect of noise quite difficult.

Can we conclude that community noise has effects that are similar to noise-induced effects reported in the laboratory literature? The similarity of our results to those reported in laboratory settings is striking. However, we still must be cautious. Replications of these results in other settings and with other populations are required before definitive conclusions are possible. To this end, our own research program includes an ongoing replication of this study, with a population exposed to traffic noise, as well as plans to collect longitudinal data on the children attending airport schools.

What conclusions can we make in regard to public policy? From a policy point of view, these data are valuable but not sufficient. At least 8 million people in this country are exposed to aircraft noise (U.S. Environmental Protection Agency, 1974), and the vast majority of noise-impacted communities have racial and social class compositions more similar to the composition of the present sample than to that of the general population (U.S. Environmental Protection Agency, Note 5). In combination with the laboratory noise literature, these data clearly suggest lending additional weight to the possible impact of aircraft noise on psychological adjustment and on nonauditory aspects of health. Replications of these results, however, would substantially increase their potential influence in the realms of both science and social policy.

APF National Media Awards for 1980

The American Psychological Foundation annually presents National Media Awards to individuals in order to recognize and encourage outstanding, accurate coverage which increases the public's knowledge and understanding of psychology. Awards are made in five categories: (1) television/film; (2) radio; (3) newspaper reporting; (4) magazine writing; and (5) books/monographs. This year the winner in each category will receive \$1,000, a citation, and an invitation to attend the APA Annual Convention in Montreal, September 1-5, 1980. The Foundation will pay travel expenses for each winner for three days.

Materials must include references to psychology and/or psychologists and depict the activities, ideas, and findings of individual psychologists or applications of psychological sciences. For example, entries that focus on social issues and mental health must include specific references to psychology and/or psychologists to be eligible. Materials nominated must have been produced or published on or after May 1, 1979, and before May 1, 1980. Nominations may be made by anyone, including the author, producer, etc. Deadline for receipt of entries is May 10, 1980. For entry forms write to Public Information Office, American Psychological Association, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

SAL00018

The American National Standards Institute, Inc. (ANSI) is the national coordinator of voluntary standards development and the clearinghouse in the U.S. for information on national and international standards.

The Acoustical Society of America (ASA) is an organization of scientists and engineers formed in 1929 to increase and diffuse the knowledge of acoustics and to promote its practical applications.

AMERICAN NATIONAL STANDARD
**Acoustical Performance Criteria,
Design Requirements,
and Guidelines for Schools**

Secretariat
Acoustical Society of America

Approved 26 June 2002
American National Standards Institute, Inc.

Abstract

This Standard provides acoustical performance criteria, design requirements, and design guidelines for new school classrooms and other learning spaces. The standard may be applied when practicable to the major renovation of existing classrooms. These criteria, requirements, and guidelines are keyed to the acoustical qualities needed to achieve a high degree of speech intelligibility in learning spaces. Design guidelines in informative annexes are intended to aid in conforming to the performance and design requirements, but do not guarantee conformance. Test procedures are provided in an annex when conformance to this standard is to be verified.

AMERICAN NATIONAL STANDARDS ON ACOUSTICS

The Acoustical Society of America (ASA) provides the Secretariat for Accredited Standards Committees S1 on Acoustics, S2 on Mechanical Vibration and Shock, S3 on Bioacoustics, and S12 on Noise. These committees have wide representation from the technical community (manufacturers, consumers, trade associations, general-interest and government representatives). The standards are published by the Acoustical Society of America through the American Institute of Physics as American National Standards after approval by their respective Standards Committees and the American National Standards Institute.

These standards are developed and published as a public service to provide standards useful to the public, industry, and consumers, and to Federal, State, and local governments.

Each of the accredited Standards Committees, operating in accordance with procedures approved by American National Standards Institute (ANSI), is responsible for developing, voting upon, and maintaining or revising its own Standards. The ASA Standards Secretariat administers Committee organization and activity and provides liaison between the Accredited Standards Committees and ANSI. After the Standards have been produced and adopted by the Accredited Standards Committees, and approved as American National Standards by ANSI, the ASA Standards Secretariat arranges for their publication and distribution.

An American National Standard implies a consensus of those substantially concerned with its scope and provisions. Consensus is established when, in the judgment of the ANSI Board of Standards Review, substantial agreement has been reached by directly and materially affected interests. Substantial agreement means much more than a simple majority, but not necessarily unanimity. Consensus requires that all views and objections be considered and that a concerted effort be made towards their resolution.

The use of American National Standards is completely voluntary. Their existence does not in any respect preclude anyone, whether he or she has approved the Standards or not, from manufacturing, marketing, purchasing, or using products, processes, or procedures not conforming to the Standards.

NOTICE: This American National Standard may be revised or withdrawn at any time. The procedures of the American National Standards Institute require that action be taken periodically to reaffirm, revise, or withdraw this Standard.

Foreword

[This foreword is for information only and is not an integral part of American National Standard *Acoustical Performance Criteria, Design Requirements, and Guidelines for Schools*.]

This standard contains 7 annexes.

This standard was developed under the jurisdiction of Accredited Standards Committee S12, Noise, which has the following scope:

Standards, specifications, and terminology in the field of acoustical noise pertaining to methods of measurement, evaluation, and control, including biological safety, tolerance, and comfort, and physical acoustics as related to environmental and occupational noise.

At the time this standard was submitted to Accredited Standards Committee S12, Noise, for final approval, the membership was as follows:

P.D. Schomer, *Chairman*
R.D. Hellweg, *Vice Chairman*
S.B. Blaeser, *Secretary*

Abbot Laboratories	D. Walton
	B. Muto (<i>Alt.</i>)
Acoustical Society of America	B.M. Brooks
	W.J. Galloway (<i>Alt.</i>)

J. Erdreich	H.L. Merck	M.E. Schaffer	W.A. Yost
D. Fagen	R. Moulder		

Suggestions for the improvement of this standard are welcome. They should be made in writing to Accredited Standards Committee S12, Noise, in care of the Standards Secretariat, Acoustical Society of America, 35 Pinelawn Road, Suite 114E, Melville, New York 11747. Telephone: +1 631 390 0215; FAX: +1 631 390 0217; e-mail: asastds@aip.org

American National Standard

ACOUSTICAL PERFORMANCE CRITERIA, DESIGN REQUIREMENTS, AND GUIDELINES FOR SCHOOLS

0 Introduction

Good acoustical qualities are essential in classrooms and other learning spaces in which speech communication is an important part of the learning process. Excessive background noise or reverberation in such spaces interferes with speech communication and thus presents an acoustical barrier to learning. With good classroom acoustics, learning is easier, deeper, more sustained, and less fatiguing. Teaching should be more effective and less stressful with good acoustical characteristics in a classroom. There can be more verbal interaction and less repetition between teacher and students when spoken words are clearly understood. Although all those in a classroom, including teachers and adult learners, will benefit, special beneficiaries are young children and persons with hearing, language, speech, attention deficit, or learning disabilities. As discussed further in annex A, conformance to this standard will improve the quality of education by eliminating acoustical barriers for all students and teachers, including those with communication disabilities. Good design and attention to detail throughout the construction or renovation process can ensure conformance to the requirements of this standard.

1 Scope, purpose, and applications

1.1 Scope

1.1.1 This standard provides acoustical performance criteria and design requirements for classrooms and other learning spaces. Annexes are included to provide information on good design and construction practices, installation methods, and optional procedures to demonstrate conformance to the acoustical performance and design requirements of this standard. This standard seeks to pro-

vide design flexibility without compromising the goal of obtaining adequate speech intelligibility for all students and teachers in classrooms and learning spaces within the scope of this standard.

1.1.2 Acoustical performance criteria are specified in this standard by limits on maximum one-hour A-weighted and C-weighted background noise levels and limits on maximum reverberation times. An objective of these performance criteria is to achieve a level of speech that is sufficiently high relative to the background noise level for listeners throughout the classroom or learning space. However, a requirement for the relative difference between speech levels and levels of background noise, usually referred to as the signal-to-noise ratio, is not within the scope of this standard.

1.1.3 The control of background noise levels in this standard is achieved, in part, by specifying the minimum noise isolation for school building elements. Noise isolation requirements are applicable to the following two types of intrusive noise.

- Noise that intrudes into the classroom or learning space from sources outside of the school building envelope. These noise sources include vehicular traffic, aircraft, industrial plants, and activity in schoolyards or from grounds maintenance. (Schools usually can control only the schoolyard and grounds-maintenance noise sources. However, when a new school site is under consideration, sound from commercial, industrial and transportation noise sources can be taken into account.)
- Noise that originates within the school building and intrudes into the classroom through classroom walls and partitions, floor-ceiling assemblies and ventilation systems. Interior noise sources can be isolated through the proper design and construction of the school building and by noise control measures applied to the building services and utilities.

1.1.4 This standard does not apply to noise generated within a classroom by its occupants. Occupant-generated noise sources include voices and the sounds of classroom activities such as the moving of chairs. Furthermore, this standard does not apply to the noise from portable or permanent built-in equipment used during the course of instruction, such as audiovisual equipment and computers. However, the background noise generated by occupants and instructional equipment can seriously degrade communication or speech intelligi-

bility in learning spaces. Recommendations are given in B5 in annex B for noise control of instructional equipment. Recommendations for background noise assessment procedures are given in E3.2.1 in annex E for such equipment. The teacher can reduce classroom activity noise directly through appropriate controls. This activity noise can also be reduced indirectly in classrooms with acoustical qualities that conform to this standard since a quiet classroom with low reverberation tends inherently to encourage children to lower the level of their voices and the sounds of their activity.

1.1.5 The following annexes are provided to support this standard.

- Annex A: Rationale for the acoustical performance criteria in this standard. (Informative)
- Annex B: Design guidelines for noise control for building services, utilities, and instructional equipment. (Informative)
- Annex C: Design guidelines for controlling reverberation in classrooms and other learning spaces. (Informative)
- Annex D: Design guidelines for noise isolation between adjacent learning spaces within a school building and noise isolation by the building facade. (Informative)
- Annex E: "Good architectural practices" and procedures to verify conformance to the standard. (Normative but Informative if conformance is not to be verified.)
- Annex F: Potential conflict between the acoustical requirements of this standard and indoor air quality (IAQ) and multiple chemical sensibility (MCS). (Informative)
- Annex G: Cautionary remarks on using supplemental descriptors for evaluating noise in classrooms and other learning spaces. (Informative)

1.2 Purpose

This standard is intended to help school planners and designers provide the acoustical qualities necessary for good speech communication between students and teachers in classrooms and other learning spaces without the use of electronic amplification systems.

1.3 Applications

1.3.1 This standard applies to classrooms and other core learning spaces of small-to-moderate size with volumes not exceeding 566 m³ (20 000 ft³) and to ancillary learning spaces of any volume.

Core learning spaces larger than the above volume limit shall be considered ancillary spaces for purposes of this standard. The standard does not apply to special-purpose classrooms, teleconferencing rooms, special education rooms, such as those for severely acoustically-challenged students or other spaces, such as large auditoria that have unique or more stringent acoustical requirements. Conformance to the requirements of this standard should be considered to be a minimum goal for the acoustical qualities of such spaces, excluding auditoria. The standard does not provide recommendations for electronic amplification or for electronic aids for persons with hearing impairment.

1.3.2 The acoustical performance criteria and design requirements of this standard apply during the design and construction of all new classrooms or learning spaces of small-to-moderate size as specified in 1.3.1. As far as is practicable, these acoustical performance criteria and design requirements also apply during the design and reconstruction of all renovated classrooms and learning spaces. However, the noise reduction and reverberation control principles in this standard also apply to larger classrooms or learning spaces. Thus, while this standard does not necessarily apply to all college and university classrooms or lecture halls, business or professional educational institutions or other adult education centers, acoustical performance criteria and design requirements similar to those in this standard may still pertain to such applications. Appropriate application of this standard to such alternative learning spaces is encouraged.

1.3.3 This standard is intended for use by school building specialists, educators, and parents. The information in annexes B, C, and D is intended for direct application by school design professionals including architects.

2 Normative references

The following standards contain provisions that, through reference in this text, constitute provisions of this American National Standard. At the time of approval of this standard by the American National Standards Institute, Inc. (ANSI), the editions indicated were valid. Because standards are revised from time to time, users should consult the latest revision approved by the American National Standards Institute (ANSI), International Electrotechnical Commission (IEC), and the American Society

for Testing and Materials (now called ASTM International). For the purposes of this standard, the use of the latest revision of a referenced standard is not mandatory. Information on recent editions is available from the ASA Standards Secretariat and ASTM International.

3 Definitions

The following definitions apply for the purposes of this standard.

3.1 General terms

3.1.1 classrooms and other learning spaces. Locations within buildings where students assemble for educational purposes.

3.1.1.1 core learning spaces. Spaces for educational activities where the primary functions are teaching and learning and where good speech communication is critical to a student's academic achievement. These spaces include, but are not limited to, classrooms, (enclosed or open plan), instructional pods or activity areas, group instruction rooms, conference rooms, libraries, offices, speech clinics, offices used for educational purposes and music rooms for instruction, practice and performance.

3.1.1.2 ancillary learning spaces. Spaces where good communication is important to a student's educational progress but for which the primary educational functions are informal learning, social

interaction or similar activity other than formal instruction. These areas include, but are not limited to, corridors, cafeterias, gymnasias, and indoor swimming pools.

3.1.2 acoustical privacy. Pertains to the acoustical attenuation between spaces that is needed to prevent conversation in one space from being understood in an adjacent space.

3.1.3 conforming learning space. Any classroom or other learning space for which the acoustical performance criteria and design requirements conform to this standard.

3.2 Terms relating to acoustical performance and design

The following terms are defined in a simplified form. Complete technical definitions are provided in ANSI S1.1.

3.2.1 noise level or sound level. Generic terms employed interchangeably throughout this standard to represent the frequency-weighted sound pressure level of an airborne sound. This descriptor is used to express the magnitude of a sound in a manner related to how the ear perceives this magnitude. Noise level or sound level is expressed in decibels, unit symbol dB.

3.2.1.1 A-weighted sound level. Sound pressure level measured with a conventional frequency weighting that roughly approximates how the human ear hears different frequency components of sounds at typical listening levels for speech. The A-weighting (see ANSI S1.4 or IEC 61672-1) attenuates the low-frequency (or low-pitch) content of a sound. A-weighted sound level is expressed in decibels, unit symbol dB.

3.2.1.2 C-weighted sound level. Sound pressure level measured with a conventional frequency weighting (see ANSI S1.4 or IEC 61672-1) that does not significantly attenuate the low-frequency (or low-pitch) content of a sound. C-weighted sound level is expressed in decibels, unit symbol dB.

3.2.1.3 one-hour-average A-weighted or C-weighted sound level. Level of the time-mean-square A-weighted or C-weighted sound pressure averaged over a one-hour period. One-hour-average sound level is expressed in decibels, unit symbol dB.

3.2.1.4 yearly average day-night average sound level. Level of the time-mean-square A-weighted

sound pressure averaged over a one-year period with 10 dB added to sound levels occurring in each nighttime period from 22:00 hours to 07:00 hours. Yearly average day-night average sound level is expressed in decibels, unit symbol dB.

3.2.2 background noise level. Sound in a furnished, unoccupied learning space, including sounds from outdoors, building services and utilities operating at their maximum levels. For the purposes of this standard, this excludes sound generated by people within the building or sound generated by temporary or permanent instructional equipment.

3.2.2.1 steady background noise. Noise from building services and utilities and from outdoor noise sources that is fairly constant over time.

3.2.2.2 unsteady background noise. Time varying noise from transportation sources, such as aircraft, vehicle traffic or from other time varying outdoor or indoor noise sources. Unsteady background noise varies substantially over time.

3.2.3 reverberation. An acoustical phenomenon that occurs in an enclosed space, such as a classroom, when sound persists in that space as a result of repeated reflection or scattering from surfaces enclosing the space or objects in the space, such as chairs or cabinets.

3.2.3.1 reverberation time. A measure of the amount of reverberation in a space and equal to the time required for the level of a steady sound to decay by 60 dB after it has been turned off. The decay rate depends on the amount of sound absorption in a room, the room geometry, and the frequency of the sound. Reverberation time is expressed in seconds, unit symbol s.

3.2.4 sound absorption and reflection. Acoustical phenomena that occur whenever sound strikes a surface. Absorbed sound is the portion of the sound energy striking the surface that is not returned as sound energy. Reflected sound is the remaining portion that bounces off the surface. The magnitude of the reflected sound in a room is determined by the amount of sound absorption at the surfaces, the room geometry, and the frequency of the sound. As distance from a sound source in a classroom increases, the sound is increasingly dominated by reflected sound.

3.2.4.1 sound absorption coefficient. A measure of the ability of a material to absorb sound and equal to the ratio of the intensity of the ab-

sorbed sound to the intensity of the incident sound. The sound absorption coefficient of a material normally varies with frequency. It ranges from about 0.2 to about 1.0 for sound-absorbing materials, to less than 0.05 for a smooth, painted concrete floor. Sound absorption coefficients measured in a laboratory (that is, in a reverberation room) can be larger than 1.0 because of test method and sample size effects.

3.2.5 acoustic isolation. A measure of the decrease in sound level (attenuation) when sound passes from one room to another, such as from one side of a wall to the other side. The passage of sound may be via an airborne path or via a structureborne path.

3.2.5.1 attenuation of airborne sound. Attenuation of sound passing through walls or ceilings, between spaces within a building, or through roofs or external walls. The attenuation of airborne sound depends on the sound reduction through these elements, on their size, on sound leakage around their periphery, on the sound absorption in the receiving space, and on the frequency of the sound.

3.2.5.2 sound transmission class. Single number rating for the acoustic attenuation of airborne sound passing through a partition or any other building element such as a wall, roof, or door as measured in an acoustical testing laboratory following accepted industry practice, abbreviation STC. A higher STC rating provides more sound attenuation through a partition.

3.2.5.3 noise isolation class. Single number rating of the noise isolation between two enclosed spaces that are acoustically connected by one or more paths, abbreviation NIC. The rating is derived from the difference in sound levels between two spaces. A higher NIC rating provides more noise isolation between the two spaces.

3.2.5.4 impact insulation class. Single number rating for the attenuation, measured in an acoustical testing laboratory, of structureborne sound through floor or floor-ceiling assemblies from floor impacts into the space below, abbreviation IIC. A higher IIC rating provides more impact sound attenuation into the space below.

3.2.5.5 field impact insulation class. Single number rating of the structureborne noise isolation provided by a floor or floor-ceiling assembly, abbreviation FIIC. The rating is derived from

Table 1 — Maximum A-weighted steady background noise levels and maximum reverberation times in unoccupied, furnished learning spaces

Learning space ^{a)}	Maximum one-hour average A-weighted steady background noise level ^{b,c)} dB	Maximum reverberation time for sound pressure levels in octave bands with midband frequencies of 500, 1000, and 2000 Hz s
Core learning space with enclosed volume < 283 m ³ (< 10 000 ft ³)	35	0.6
Core learning space with enclosed volume > 283 m ³ and ≤ 566 m ³ (> 10 000 ft ³ and ≤ 20 000 ft ³)	35	0.7
Core learning spaces with enclosed volumes > 566 m ³ (20 000 ft ³) and all ancillary learning spaces	40 ^{d)}	e)

a) See 3.1.1.1 and 3.1.1.2 for definitions of core and ancillary learning spaces.

b) See 4.3.1 for limits on unsteady (time varying) background noise levels.

c) See 4.3.2 for other limits on background noise from building services and utilities including C-weighted steady background noise levels.

d) When corridors are used solely for conveyance of occupants within the school building and structured learning activities do not occur, the A-weighted steady background noise level limit for such corridors may be increased to 45 dB. The use of corridors for formal learning purposes should be avoided.

e) See C3.3 in annex C for recommendations on control of reverberation in these spaces.

the sound levels measured in the receiving room when a standard tapping machine is operating on the floor assembly in the source room above. The higher the FIIC rating, the more the impact noise isolation between the two spaces.

4 Acoustical performance criteria and noise isolation design requirements and guidelines

4.1 Introduction

Acoustical performance criteria and design requirements are contained in the following sub-clauses. The performance criteria shall apply to classrooms and other core learning spaces and to ancillary learning spaces. For purposes of this standard it shall be assumed that the learning spaces are furnished consistent with their use and the building is unoccupied with doors and windows closed. Acoustical design requirements for minimum noise isolation apply only to fully enclosed classrooms and learning spaces.

4.2 Performance criteria for background noise and reverberation time

The one-hour-average A-weighted steady background noise level and the reverberation times shall not exceed the limits specified in table 1. The limits for the background noise shall apply for the following conditions:

- 1) for the noisiest continuous one-hour period during times when learning activities take place;
- 2) exterior and interior noise sources are operating simultaneously;
- 3) interior sources are operating as defined in 4.3.2; and
- 4) portable and permanent (built-in) instructional equipment, such as computers and audio-visual equipment, are turned off.

While designing to conform to both acoustical performance criteria in table 1 is required, conformance to the background noise level criterion is the more important of the two. When optional conformance testing is carried out, the tolerances specified in 4.7 reflect this relative importance.

4.3 Background noise levels

4.3.1 Unsteady background noise from transportation noise sources. School facilities should be sited and designed to limit the noise levels inside learning spaces from transportation noise sources, such as aircraft, road vehicles and trains. (See D2.3 in annex D for further guidance on outdoor-indoor noise isolation and school siting.)

The limits on A-weighted background noise levels in table 1 shall be increased by 5 dB when the noisiest hour is dominated by transportation noise and the following conditions apply to the A-weighted SLOW time-weighted background noise level. For core learning spaces with enclosed volumes not greater than 566 m³ (20 000 ft³), this level does not exceed 40 dB for more than 10% of this noisiest hour. For core learning spaces with enclosed volumes greater than 566 m³ (20 000 ft³) and for ancillary learning spaces, this level does not exceed 45 dB for more than 10% of this noisiest hour. (See E3.7.2 in annex E for a measurement method for this evaluation.)

4.3.2 Background noise from building services and utilities. Steady background noise from HVAC systems and other building services and utilities operating simultaneously shall conform to the requirements of table 1 for all operating modes (for example, cooling, heating, ventilating, and dehumidifying) and at the maximum operating conditions (for example, maximum fan speed with all lights on). Unsteady background noise levels from plumbing systems (for example, toilets and bathing rooms) operating at their noisiest condition, shall also conform to the limits in table 1 taking into consideration their normally limited operating time within any one hour. (See annex B for guidelines on control of noise from HVAC systems, building services, and utilities.)

4.3.2.1 Limits on steady C-weighted background noise levels from building services and utilities. The maximum one-hour-average C-weighted steady background noise levels from the combination of HVAC systems, lighting, and other building services and utilities operating simultaneously shall not exceed the limits on A-weighted steady background noise levels in table 1 by more than 20 dB.

4.3.2.2 Limits on disturbing sounds from building services and utilities. Disturbing sounds, such as rumble, hum, buzz, whine, hiss, or whistle, from HVAC systems and other building services

and utilities shall be controlled so as to not interfere with speech communication or be distracting or annoying to the occupants of the learning spaces.

4.3.2.3 Limits on time-varying noise levels from building services and utilities. The A-frequency-weighted and SLOW time-weighted noise level at any usable location in a room, from HVAC systems and other building services operating as specified in 4.3.2 shall not vary by more than 3 dB during any 5-s period. This shall be measured with a sound level meter conforming to at least the Type 2 requirements of ANSI S1.4 or the class 2 requirements of IEC 61672-1. Such time-varying noise shall be considered to be caused by the building systems and services, unless the noise is clearly recognized as being produced by transportation noise sources, such as road traffic or aircraft, addressed in 4.3.1.

4.3.3 Background noise from instructional equipment. For this standard, noise from instructional equipment is not included in the steady background noise. However, control of such noise, especially that from permanent built-in instructional equipment, should be carefully addressed in the planning stages for new and renovated schools. (See B5 in annex B for guidance on applicable noise control measures for such instructional equipment.)

4.4 Reverberation times

The maximum allowable reverberation times in unoccupied, furnished core learning spaces are specified in table 1 for core learning spaces with enclosed volumes of not more than 566 m³ (20 000 ft³). Design guidelines for controlling reverberation time in learning spaces of all sizes and for selection and proper certification for any acoustical materials applied to control this reverberation are presented in annex C.

4.5 Noise isolation design

The first and most cost effective step in achieving good noise isolation between learning spaces and other spaces in a school is accomplished in the facility planning stage. This includes optimizing the location of noisy spaces and activities to protect sensitive learning spaces. Where this is not possible, adequate noise isolation is needed.

4.5.1 Need for noise isolation. The acoustical performance criteria for background noise levels in

Table 2 — Minimum STC ratings required for single or composite wall, floor-ceiling, and roof-ceiling assemblies that separate an enclosed core learning space from an adjacent space

Adjacent space			
Other enclosed or open plan core learning space, speech clinic, health care room and outdoors ^{c)} 50	Common use and public use toilet room and bathing room 53	Corridor, ^{a)} staircase, office or conference room ^{a,b)} 45	Music room, mechanical equipment room, ^{d)} cafeteria, gymnasium, and indoor swimming pool 60

- a) For corridor, office, or conference room walls containing doors, the basic wall, exclusive of the door, shall have an STC rating as shown in the appropriate column in this table. The entrance door shall conform to the requirements of 4.5.5.
- b) When the need for acoustical privacy is critical, the minimum STC rating of the partitions around an office or conference room shall be increased to 50.
- c) An STC rating of 50 is the minimum for the exterior walls and roofs of a core learning space. However, this rating does not ensure conformance to the background noise limits in table 1 for noise from major outdoor noise sources. See D2.3 in annex D for further guidance on the selection of appropriate STC ratings.
- d) When the adjacent space is a mechanical equipment room containing fans circulating 140 m³/min. (5000 ft³/min.) or more, the minimum STC rating shall be 60. When the fan circulation is less than this rate, the STC rating may be as low as 45 providing the maximum A-weighted steady background noise level in the adjacent core learning space does not exceed 35 dB. The minimum STC rating shall include the effect of entry door(s) into the mechanical equipment room.

4.2 and 4.3 apply to unoccupied facilities. However, in occupied facilities, activity noises generated in one space can be transmitted through walls, floors, ceilings, and doors to adjacent learning spaces, thus contributing to the overall background noise level in those spaces. Adequate sound isolation is required to limit noise transmission between core learning spaces and adjacent spaces in occupied facilities. The minimum STC ratings of table 2 and table 3 are intended to provide this noise isolation for normal activities in adjoining spaces.

Certain educational styles (such as open plan and group learning) intentionally avoid the use of full enclosures between learning groups. Sometimes, partial height sound barriers or no barriers at all separate adjacent learning groups. Adequate noise isolation between adjacent learning groups cannot be assured unless each learning group is fully enclosed by ceiling-height sound barriers. Because of the inherent low noise isolation, partially enclosed or unenclosed learning spaces are not recommended when good speech communication is desired.

In occupied multistory educational facilities, the transmission of impact noise through the floor of the room above to the learning space below also contributes to the overall background noise level.

To limit impact noise disturbances in learning spaces, this standard also provides minimum impact insulation class (IIC) design requirements for the floor-ceiling assemblies above learning spaces for multistory educational facilities.

As discussed further in D1 in annex D, the noise isolation requirements of this standard are similar in concept to those in existing national and international building codes.

4.5.2 Noise isolation design requirements. In this standard, noise isolation is specified by the minimum values for the STC and IIC ratings for single and composite building elements that may provide acceptable noise isolation for learning spaces. Selection of these minimum ratings, achieved during architectural design, is the basis for limiting the transmission of background noise from external and interior sources into an enclosed learning space. After construction, a field measurement may be made to verify the noise isolation achieved [see 4.6 (3)].

When high noise isolation is required, as for music rooms, flanking of sound along common floors, walls, and roofs can become a limiting factor unless controlled with proper breaks in sound transmission paths or other similar treatments. There are many publications that provide details on de-

Table 3 — Minimum STC ratings recommended for single or composite wall, floor-ceiling and roof-ceiling assemblies separating an ancillary space from an adjacent space

Receiving ancillary Learning space	Adjacent space Corridor, ^{a)} staircase, common use and public use toilet and bathing room ^{b)}	Music room	Office or conference room ^{a)}	Outdoors ^{e)}	Mechanical equipment room, ^{f)} cafeteria, gymnasium or indoor swimming pool
Corridor	45	60 ^{c)}	45 ^{d)}	45 ^{c)}	55 ^{c)}
Music room	60	60	60	45	60
Office or conference room	45	60	45 ^{d)}	45	60

- a) For corridor, office or conference room walls containing entrance doors, the STC rating of the basic wall, exclusive of the door, should be 45. The entrance door should conform to the requirements of 4.5.5.
- b) The STC rating for an ancillary space/toilet partition does not apply when the toilet is private and connected to a private office. An STC rating higher than 45 may be required for separating a quiet office or conference room from a common use or public use toilet or bathing room.
- c) When the corridor will not be used as an ancillary learning space, the minimum STC rating may be reduced to not less than 45 or to not less than 40 for an exterior wall. Use of corridors as ancillary learning spaces should be avoided when they are located next to the noisy spaces indicated in the table by the high STC ratings.
- d) When the need for acoustical privacy is critical, the STC rating should be increased to 50.
- e) See D2.3 in annex D for further guidance on the selection of appropriate STC ratings.
- f) NOTE d) of table 2 applies except that the STC rating may be as low as 40 providing the maximum A-weighted steady background noise level in the adjacent ancillary learning space does not exceed 40 dB.

sign and construction of separating partitions that may achieve the required STC ratings. Annex D provides guidelines and references for such noise isolation design and construction.

4.5.3 Sound transmission class (STC) ratings

4.5.3.1 Core learning spaces. The minimum STC ratings in table 2 shall be employed for the acoustical design of wall, floor-ceiling and roof assemblies that separate enclosed or open plan core learning spaces from adjacent spaces. When the assembly includes two or more elements, such as doors or windows, the STC of this composite assembly also shall conform to the requirements of table 2.

Composite assemblies are walls, floor-ceiling and roof-ceiling constructions composed of more than one element (for example, a wall with a door, window, or penetrations by HVAC ducts or other services). (See NOTE a) to table 2 for special requirements for doors in corridor, office or conference room walls.)

Walls and floor-ceiling assemblies may not maintain their design STC rating if penetrations or openings for piping, electrical devices, recessed

cabinets, soffits, or heating, ventilating or exhaust ducts are unsealed. For this reason, all penetrations in sound-rated partitions shall be sealed and treated to maintain the required ratings. The STC rating requirements of table 2 shall also be employed for the design of temporary partitions that subdivide a learning space.

4.5.3.2 Ancillary learning spaces. Recommendations are given in table 3 for STC ratings for partitions (that is, walls and floor-ceiling assemblies) that enclose an ancillary learning space or that separate two ancillary spaces. When the partition includes two or more elements, such as doors, windows, or penetrations of the partition for HVAC ducts or other services, the STC of this composite construction also should conform to the recommendations of table 3.

4.5.4 Composite partitions. The required minimum STC ratings in table 2 apply to single or composite partitions. Basic wall assemblies (except those identified in NOTE a) for table 2) which contain doors or windows with STC ratings less than those given in table 2, will require higher STC ratings to conform to the required minimum STC ratings of the composite construction. This design

technique is also recommended for partitions enclosing the ancillary learning spaces covered by table 3. A method for estimating the STC rating of composite partitions is provided in D2.4 in annex D.

4.5.5 Entry doors into classrooms and other core learning spaces. To conform to the STC requirements of table 2 for composite walls, entrance doors into classrooms or other core learning spaces would be expected to have laboratory STC ratings of 30 or more in their operable condition. The STC rating for interior entry doors into, or between, music rooms shall be not less than 40. The location of classroom entry doors across a corridor should be staggered to minimize noise transmission between these classrooms.

Provisions should be made to ensure that the perimeter seals of sound rated doors are well maintained. Seals for entrance doors should be inspected and adjusted, as necessary, every six months. The gaskets of door seals should never be painted.

4.5.6 Impact Insulation Class (IIC) rating. The floor-ceiling assemblies of normally occupied rooms located above core learning spaces shall have IIC ratings of at least 45 and preferably 50. If a room below is an ancillary learning space, the floor-ceiling assembly shall have an IIC rating of at least 45. These IIC ratings shall apply without carpeting on the floor in the room above. In new construction, gymnasiums, dance studios or other high floor impact activity, shall not be located above classrooms or other core learning spaces. For refurbishment of existing structures, if it is not possible to avoid such an incompatible condition, the IIC rating of the separating floor-ceiling assembly shall be at least 70 when located above a core learning space with an enclosed volume not greater than 566 m³ (20 000 ft³); 65 when located above a core learning space with an enclosed volume greater than 566 m³ (20 000 ft³); and 65 when located above an ancillary learning space. Clause D2.5.1 in annex D provides further guidance on impact noise isolation.

4.6 Conformance to acoustical performance criteria and noise isolation design requirements

It is recommended that conformance to the acoustical performance criteria and noise isolation design requirements be verified by test. However, this standard does not require testing to demon-

strate conformance. When optional tests are performed to verify conformance with the requirements and recommendations of this standard, the following procedures shall be followed.

1) Tests to demonstrate conformance to the limits on background noise levels in table 1, 4.3.1, and 4.3.2.1 shall be performed in accordance with the procedures in E3 of annex E. If necessary, appropriate tests shall be performed to demonstrate conformance with the limits on disturbing or time varying noise from building services and utilities given in 4.3.2.2 and 4.3.2.3, (See E3.7.3 in annex E.)

2) Conformance to the limits on reverberation times in table 1 shall be verified by calculation or by measurement procedures in conformance, or equivalent, to those in E4 of annex E.

3) Conformance to the minimum sound transmission class (STC) design requirements of table 2 and the design recommendations of table 3 shall be verified by field determination of the noise isolation class (NIC) as described in E5.1 in annex E. However, it shall be considered unnecessary to verify conformance to these noise isolation design requirements and recommendations if conformance to the noise limits of table 1 is demonstrated for the noisiest hour when learning takes place.

4) Conformance to the impact insulation class (IIC) requirements of 4.5.6 shall be verified by the field testing procedures in E5.2 in annex E.

4.7 Conformance tolerances

When conformance testing or evaluation is performed, conformance to the requirements and recommendations of this standard is demonstrated if each of the following is achieved. No additional tolerances shall be allowed for the test methods or instruments used for such demonstrations except as specified in this subclause.

1) The measured A-weighted steady or unsteady background noise levels do not exceed the limits specified in table 1 and 4.3.1, respectively, by more than 2 dB. The C-weighted steady background noise levels do not exceed the limits in 4.3.2.1 by more than 2 dB.

2) Mean reverberation times, if calculated, do not exceed the limits in table 1 or, if measured, do not exceed the limits in table 1 by more than 0.1 s.

3) All separating walls and floor-ceiling assemblies have NIC ratings that are not less than a rating 5 points below the required STC rating in table 2 or

the recommended rating in table 3. For example, for a partition between a classroom and a speech clinic, conformance to the minimum STC rating of 50 in table 2 is achieved if the NIC rating is not less than 45.

4) All floor-ceiling assemblies separating occupied spaces from learning spaces below have a field impact insulation class (FIIC) rating that is not less than a rating 5 points below the design requirement specified in 4.5.6.

Annex A (Informative)

Rationale for acoustical performance criteria

A1 Introduction

The school classroom is an environment in which spoken language communication facilitates and enables students to learn essential academic, social, and cultural skills. Thus, the classroom serves as a communication channel for learning and should be free of acoustical barriers. This informative annex defines the perceptual, educational, and developmental rationale for the acoustical performance criteria specified in table 1 of this standard. These rationales allow determination of the signal-to-noise ratio and reverberation time that can ensure most children, adult learners, and teachers full and equal access to spoken communication within the classroom. The acoustical performance criteria in the standard are derived from empirical studies of classroom noise and reverberation and their effects on speech communication.

A1.1 Educational rationale

Intensive and continuous learning of social, intellectual, and communication skills occurs throughout childhood. A wide range of educational research studies [A1]* has shown that learning is predicated on the ability to communicate with spoken language, and that language input and language proficiency form the bases for most cognitive skills. Additionally, other research [A2] has shown that perception of spoken language provides the foundation for the ability to read and write. Communication with spoken language is essential to most classroom learning activities. Typically, as much as 60% of these activities involve students listening to and participating in spoken communications with the teacher and other students. The central role of spoken language in classroom learning underscores the need for a clear communication channel accessible to all students and teachers.

A1.2 Perceptual rationale

Communication with spoken language can occur successfully only when speech intelligibility is high. Research in speech perception [A3] has found that when the background noise is very low, speech intelligibility depends in part on the absolute sound level of the speech, and in part on the absence of excessive reverberation.

A1.3 Speech intelligibility in background noise

Most speech communication in classrooms occurs in the presence of background noise. When background noise is present, intelligibility depends on the sound pressure level of the speech and also on the level of the speech relative to the level of the noise, that is, the signal-to-noise ratio (SNR) [A4]. The sound levels of both the speech and noise are expressed as A-weighted sound levels in decibels. The relative speech to noise level, or SNR, expressed in decibels, is the sound level of the speech alone in the presence of background noise minus the sound level of the background noise.

Intelligibility increases as the SNR increases, either by raising the speech level or by decreasing the noise level. Speech perception research [A5] has shown that individuals with hearing impairments, speech and language disorders, or limited English proficiency require more favorable signal-to-noise ratios than individuals without these impairments or disorders to achieve high levels of speech intelligibility.

A1.4 Speech intelligibility in reverberant environments

Classrooms are enclosed spaces in which sound produces reverberation. Reverberation times in

*"[AX]" designates reference [AX] in the bibliography at the end of this annex.

excess of 0.4 s to 0.6 s reduce speech intelligibility both in quiet and in noise.

When both background noise and excessive reverberation are present, their effects on speech intelligibility are additive for individuals with normal speech, language, and hearing abilities. Speech perception research [A4, A6] has shown that individuals with impaired speech, language, and hearing abilities require signal-to-noise ratios that are at least 3 dB more favorable to offset their susceptibility to the negative effects of reverberation, as compared with individuals without impairments.

A1.5 Selective acoustical barriers to learning produced by background noise and reverberation

If spoken communication in the classroom becomes inaudible or unintelligible for some students and teachers because of excessive background noise or reverberation, a clear communication channel is no longer accessible to these children, creating a selective acoustical barrier to learning. Neither the child's ability to understand in quiet nor the adult teacher's ability to understand in the noisy classroom is a good predictor of when such barriers might exist. This difficulty in prediction is also exacerbated by a young child's unawareness of these barriers to learning.

A1.6 Scholastic achievement and the classroom acoustical environment

The link between the acoustical barriers in the classroom and the scholastic achievement of students has been evaluated in studies supporting the objectives of this standard. The reading scores of 2nd to 6th grade children in a school exposed to noise from a nearby elevated urban train track [A7, A8] were compared in quieter and noisier classrooms. The students, comparable in all respects, were receiving the same type of instruction. However, the children in the lower grades and noisier classrooms were three to four months behind in reading scores relative to those in the quieter classrooms and as much as 11 months behind for the higher grades. After a subsequent reduction of the track noise by 3 to 8 dB, the reading scores in the noisy classrooms were still approximately one year behind those in the quiet classrooms.

A major, controlled study of noise effects on scholastic achievement [A9] was carried out in 81

classrooms in 15 socio-economically matched Los Angeles schools located different distances from freeways. These differences caused the traffic-noise-generated indoor background noise to differ by up to 19 dB between the noisiest and quietest classrooms. Reading and math grade-equivalent scores evaluated for English-proficient students in 3rd and 6th grade classes, showed a decrease of approximately 2.2 years between the noisiest and quietest schools for the 6th grade classes and 0.7 years for the 3rd grade classes. This prominent noise effect on grade differences in scholastic achievement is believed the result of either differences in teaching style between grades or, more insidious, a possible cumulative, compounded effect of poor acoustics on learning as a student progresses through school.

A study of 13 schools in the United Kingdom [A10] compared their acoustical environment and corresponding speech communication conditions and teacher satisfaction before and after sound—absorbing treatment of the ceilings. After treatment, the average A-weighted background noise level in the unoccupied classrooms dropped from 45 dB to 40 dB reflecting the decrease in reverberant background noise level. The average reverberation time in the unoccupied rooms dropped from 0.7 to 0.4 seconds. The acoustically treated classrooms were favored by the teachers and pupils, who reported a greater ease of communication and increased student performance.

A2 Developmental rationale

Young children are more susceptible than adults to the effects of background noise and reverberation on communication with spoken language. Because of this susceptibility, young children also require more favorable classroom signal-to-noise ratios and reverberation times to achieve the same level of speech intelligibility as adults do. Developmental status, linguistic and cognitive proficiency, temporary hearing impairments, and early receptive and expressive language disorders are all factors that affect the greater susceptibility of young children to background noise and reverberation. For example, in a longitudinal study [A11] of preschool children in acoustically-treated or non-treated rooms in a child-care center, the children in the treated rooms scored higher in number-letter-word recognition after one year of reduced noise exposure than their cohorts in the non-treated rooms.

A2.1 Developmental status

Speech communication in unfavorable listening conditions is a complex, high-level task requiring a level of neurological maturity that is usually achieved only by 13 to 15 years of age. Consequently, young children may require more favorable signal-to-noise ratios and shorter reverberation times than older children require. Speech perception research [A12] has shown that 6-year-old children with normal hearing and normal language proficiency require signal-to-noise ratios 2 dB more favorable than 15-year-old children to achieve the same level of speech intelligibility. The 15-year olds, however, required the same signal-to-noise ratios as adults. In quiet listening conditions, the adults and both age groups of children had good speech intelligibility.

A3 Hearing impairment

Young children are also more susceptible to temporary conductive hearing impairment caused by ear infection (otitis media) than adults. Demographic research [A13] has identified otitis media as the most common medical disorder in young children, with an estimated incidence as high as 25% to 30% among kindergarten and first grade children. Other research [A14] has found an incidence greater than 10% of mild high-frequency sensorineural hearing impairment among children 6 to 19 years of age. Signal-to-noise ratio improvements of 3 dB to 5 dB together with increases in absolute speech sound levels of 10 dB to 30 dB are necessary for children with these impairments to achieve the same level of speech intelligibility in classrooms with high background noise.

A4 Language proficiency and language disorders

Children with expressive and receptive language disorders may also require more favorable signal-to-noise ratios to achieve good intelligibility, as compared with children without these disorders. Research studies have shown, for example, that children with language disorders have 10% to 40% poorer speech intelligibility in background noise than children without these disorders, despite comparable results in quiet environments. Children for whom English is not the first or primary language may have limited English proficiency. These children are often learning English in school at the same time that they are learning the regular academic curriculum.

Limitations in vocabulary and in the ability to "fill in the blanks" when partial communication occurs in difficult listening situations have been shown to reduce intelligibility for children with limited English proficiency [A15], again despite normal intelligibility in quiet environments. These children may require 2 to 5 dB more favorable signal-to-noise ratios in difficult listening situations to achieve the same level of intelligibility as children with normal English proficiency.

A related speech disorder problem caused by poor classroom acoustics stems from the increased frequency of voice impairments and their consequences for communication. In noisy or reverberant classrooms, teachers are more likely to have to raise their voices. The results are higher incidences of voice impairment among teachers and children have greater difficulty hearing verbal instruction presented by voice-impaired teachers in such noise or reverberation.

A5 Determining appropriate acoustical performance criteria and noise isolation design requirements

The acoustical performance criteria for this standard are expressed in table 1 in terms of background noise levels and reverberation times. Noise isolation design requirements for this standard are given in table 2, in terms of sound transmission class (STC) ratings for enclosed learning spaces, despite the fact that the rationale for these criteria and requirements is based on absolute and relative levels of speech. The terminology of the standard is necessary because speech levels are difficult to prescribe or standardize. However, the research literature on classroom speech sound levels can be used to specify the expected range of speech sound levels seen throughout a classroom. These sound levels, together with knowledge of the signal-to-noise ratios and reverberation times necessary for high intelligibility, were used to determine the requirements for acceptable background noise levels and reverberation times for unoccupied, furnished classrooms in table 1. The background noise level criteria were, in turn, used to determine acceptable STC ratings for walls, ceilings, and floors, in table 2, that will prevent noise from adjacent occupied enclosed spaces from exceeding the background noise level criteria in the classroom.

A5.1 Classroom speech levels

Research studies [A16] of sound levels for conversational speech and teachers' classroom speech [A17] show for the latter, the average A-weighted sound level is 67 dB at 1 m in a quiet classroom. In typical classrooms with little reverberation, speech sound levels in the rear of the classroom may be as low as 50 dB. The criteria for background noise levels in this standard assume minimum speech sound levels will be 50 dB anywhere in the classroom.

A5.2 Background noise levels

The 35 dB acoustical performance criteria for steady classroom background noise levels in table 1 were based on the assumption that a signal-to-noise ratio of at least +15 dB was necessary to ensure that noise will not be a barrier to learning within a classroom. Assuming a minimum speech level of 50 dB, a signal-to-noise ratio of at least +15 dB will always be achieved if the background noise level does not exceed 35 dB. The choice of +15 dB for the signal-to-noise ratio was based on several considerations. The American Speech-Language-Hearing Association [A18] recommends at least a +15 dB signal-to-noise ratio in classrooms to ensure that children with hearing impairments and language disabilities are able to achieve high speech intelligibility.

In addition, the research literature summarized in this annex also supports a signal-to-noise ratio of +15 dB.

Normal adults typically require 0 dB signal-to-noise ratios for high speech intelligibility when listening to simple and familiar speech material for short periods of time. An additional 2 dB is needed to compensate for neurological immaturity; an additional 5 dB is required to compensate for sensorineural and conductive hearing losses; an additional 5 dB is required for limited English proficiency and language disorders; and an additional 3 dB is required to compensate for the effects of excessive reverberation. These additional requirements for classrooms total 15 dB over that of normal adults, or a signal-to-noise ratio of +15 dB. This conclusion does not include any further increase in the signal-to-noise ratio that may be associated with the fact that children in the lower grades may be listening to unfamiliar speech material.

A5.3 Reverberation times

According to available research data, the effects of reverberation on speech intelligibility are controlled primarily by reverberation times at the three frequencies specified in table 1: 500, 1000, and 2000 Hz. Based on this research, it was assumed that reverberation times of 0.6 s, or less, in small and mid-sized classrooms and 0.7 s, or less, in larger classrooms will not degrade speech intelligibility excessively as long as signal-to-noise ratios of +15 dB or better are maintained. (The reverberation times in table 1 are given for unoccupied, furnished spaces. For occupied spaces, the reverberation times are expected to be 0.1 s to 0.2 s less than those in table 1.) These signal-to-noise ratios will be achieved if the background noise performance criteria also are satisfied. Thus, the acoustical performance criteria for both steady background noise levels and reverberation times should be satisfied simultaneously to ensure the elimination of acoustical barriers to classroom learning.

Annex B (Informative)

Design guidelines for noise control for building services, utilities, and instructional equipment

B1 Introduction

HVAC systems and other building services and utilities are complex systems of mechanical, electrical, and plumbing components supplied by many different manufacturers. This observation is particularly true for most HVAC systems designed for specific projects. Noise from these building systems can be generated and transmitted to a room in a wide variety of ways. Responsibility for providing an adequate noise control design that will allow conformance to the background noise level limits in table 1 resides with the architect and the architect's design subcontractors. During construction, responsibility for implementing the noise control design for each element of the building services may rest with each individual subcontractor, but the general contractor is likely to have overall re-

sponsibility to ensure that the design and implementation conforms to the background noise level limits in table 1.

B2 HVAC noise control

Specific limits on the maximum allowable A-weighted and C-weighted background noise level from HVAC equipment are given in 4.3. To achieve these limits, an HVAC system should be designed with noise control in mind. The following are some of the minimum features that should be employed for HVAC systems intended for any learning facility.

1) Unducted systems should not be employed since the sound they produce is inherently unable to conform to the background noise level criteria in table 1.

2) All grilles and diffusers (air devices) should be selected to have a catalog Noise Criteria (NC) rating of NC 18 or less for a single diffuser, providing the NC catalog ratings are based on a correction of 10 dB for sound absorption in the room. [B1]

NOTE Noise Criteria (NC) is a single number rating of room noise based on comparison of the octave-band sound pressure level spectrum of a noise with standardized octave-band sound pressure level contours that include low-frequency sound (see annex G).

3) Airflow velocities in trunk ducts should not exceed 4.1 m/s (800 ft/min). Branch ductwork sizes should match the air device's duct connection size. Duct silencers will be required inside the air-handling unit or in the main supply and return air ducts in most systems.

4) All ductwork should be fabricated and installed so as to achieve a low static pressure loss in accordance with procedures in the Sheet Metal & Air-Conditioning Contractors National Association (SMACNA) for HVAC System Duct Design, [B2]. To achieve the rated performance of air diffusers, the plenum depth should be the equivalent of at least three to four diameters of the duct going to the diffuser.

5) All rotating equipment and equipment with static pressure control dampers should be 3.3 m (10 ft), or farther if possible, from the classroom. HVAC fan equipment serving more than one classroom should be farther from the classrooms than equipment serving only one classroom.

6) Centrifugal fans with airfoil-shaped blades should be used in most cases in order to achieve the background sound levels required for the learning spaces. Centrifugal fans with forward curved blades should be avoided (especially with central air distribution systems) because this fan design typically generates excessive low-frequency noise when the total static pressure is greater than 2 inches of water.

7) Ductwork serving adjacent learning spaces should include sound attenuators or sound-absorbing duct lining (if required), or both, to reduce crosstalk through the duct system. The attenuation should be sufficient to preserve the noise isolation between the adjacent learning spaces.

8) To minimize HVAC noise transmission into core learning spaces, variable air volume (VAV) boxes and fan-powered boxes should not be located over these spaces. Instead, the elements should be lo-

ated over less sensitive spaces, which may include corridors.

The above guidelines are examples of the many noise control provisions that may be needed when designing an HVAC system. Before finalizing any HVAC noise control design, considering the very large number of HVAC systems types that may be employed for schools, the facility designer or the responsible subcontractor should consult one or more references such as those listed in clause B7. The ASHRAE Handbooks, [B3-B5] are especially helpful to assist in achieving an HVAC system design that will conform to the required minimum level of steady background noise. HVAC manufacturers should be able to provide useful design or noise-rating information for their systems or components [B6]. References [B7], [B8] and [B9] provide further guidance on noise control for HVAC systems and other building services.

B3 Noise control considerations for electrical equipment and systems

Significant background noise in a learning space can be produced by electrical equipment and its installation. Two such sources of noise are electrical fixtures and light fixture ballasts. Light fixtures with low-noise ballasts should be used in learning spaces to assist in conforming to the requirements of table 1 for background noise levels. Improper installation of electrical or cable boxes can degrade sound isolation between rooms. For single stud walls, electrical outlet boxes on opposing walls should never be in the same stud space. For dual-stud walls, the boxes should be separated by at least 0.6 m (24 inches). If back-to-back electrical boxes are necessary in double stud walls, either of the following methods should be used. The boxes should be enclosed in full gypsum board enclosures that do not contact the framing of the other row of studs and have all joints sealed with caulking or both boxes should be of the vapor-barrier type that are properly caulked and sealed.

B4 Plumbing systems noise control

Water flow noise from plumbing systems can be a significant contributor to the background noise level in a learning space. To minimize noise from plumbing fixtures and piping located adjacent to core and ancillary learning spaces, consideration should be given to the following installation details.

- 1) Run piping above corridor ceilings, not above learning spaces.
- 2) Locate restrooms away from classrooms.
- 3) Use cast iron waste water pipes, when possible. Plastic piping may require special care during installation to ensure quiet operation and should be wrapped with one or more layers of sound-attenuating material or, for plastic waste pipe, wrapped with sound-absorbing material and boxed in with gypsum wallboard.
- 4) Isolate all water piping from the building walls and structure using foam rubber wrapping or resilient clamps and hangers.
- 5) When it is necessary for a plumbing wall chase to be adjacent to a learning space, the wall should employ double stud construction [with a minimum 2.5 cm (1 inch) gap between the two rows of studs] with two layers of gypsum board on the classroom side and sound-absorbing insulation batts in both stud cavities.
- 6) Reduce the pressure of the supply water as much as possible and employ trapped-air water-hammer arrestors for water supply pipes serving flush or solenoid valve fixtures to reduce water hammer noise.
- 7) Use water siphon jet fixtures instead of blowout fixtures.
- 8) Inspect all plumbing installations for conformance to the noise control features before sealing the walls.

B5 Noise control for instructional equipment used in a classroom

As stated in 1.1.4, the background noise from portable or permanent, built-in equipment used during the course of instruction, such as audio-visual equipment or computers, is not within the scope of this standard. Cooling fans or other internal rotating components usually generate this noise. Because this noise can increase the background noise level in learning spaces, this equipment should be carefully selected and located to minimize its noise impact on the learning process. Except for computers, standards for the acoustical emission characteristics (for example, sound power level) of such equipment are not currently available.

Such instructional equipment, when operating, should be located as far as possible from students

or placed in noise-isolating enclosures. This procedure is especially important and practical for built-in audio-visual systems or overhead projectors. For such built-in equipment, a design goal should be to ensure that its operation will not cause the total one-hour average background noise level to exceed the limits specified in table 1 while HVAC systems and other building services and utilities are also operating.

The designer of the noise-control features should actively seek to determine whether potentially noisy instructional equipment is planned for permanent or long-term installation in a noise-sensitive instructional space. If so, appropriate noise isolating enclosures should be included in the classroom design planning.

The background noise level in a learning space containing a large number of computers, each with its own cooling fan, may be well above the background noise limits in table 1. In such learning spaces, special consideration should be given to noise control by selection of low-noise computers and the addition of more sound-absorbing treatment than needed to conform to the reverberation criteria in table 1 in order to minimize the reverberant level of this background noise. Sound-absorbing partial barriers may be needed between computer stations.

B6 Conforming to the limits for background noise level

Conforming to the noise level criteria specified in table 1 and the design techniques discussed in this annex may require coordinated action by the architects for design of the school building, the general building contractor, the school-facility design staff, the equipment suppliers, and a person with professional experience in building noise control technology.

Selection of a person experienced in building noise control technology is the ultimate responsibility of the owner or designer of the educational facility. However, such a person should be able to provide evidence of professionally recognized expertise in noise-control technology for building services, utilities, and equipment, or be employed by a firm with the same professionally recognized expertise.

The fact that a project has a person trained in building noise control technology on the design team does not ensure conformance to the provi-

sions of this standard. Workmanship and the quality of products used on the project are also major factors in achieving the required acoustical environment in all learning spaces. The best design can be negated by poor workmanship and use of products that do not conform to published performance specifications.

Manufacturers of school building services equipment, utilities (for example, HVAC and lighting) and instructional equipment usually can supply noise emission levels for their products. This information should be evaluated carefully during the equipment selection process.

Annex C (Informative)

Design guidelines for controlling reverberation in classrooms and other learning spaces

C1 Introduction

The amounts and locations of sound absorption treatments needed to limit reverberation are important considerations for good acoustical characteristics in learning spaces. Excessive reverberation can reduce the understanding of spoken words. Conversely, too much sound-absorbing treatment, especially in dedicated lecture rooms, can reduce beneficial early sound reflections causing speech levels from a talker to fall off rapidly with distance and thereby reduce speech intelligibility for distant listeners. This annex provides design guidelines for the control of reverberation in learning spaces by the addition of sound-absorbing materials. The guidelines are intended to assist

in achieving conformance to the reverberation time criteria in table 1.

C2 Procedure to estimate the amount of sound-absorbing material needed to achieve the design goal for reverberation time

The first step in developing an estimate of the minimum required area of acoustical treatment for installation in a learning space is to apply the Sabine formula [C1]. According to this formula, the minimum total sound absorption A needed to achieve a reverberation time of T_{60} seconds or less in a room of enclosed volume V is given by:

$$A \geq kVT_{60} \quad (C.1)$$

The constant $k = 0.161$ s/m when volume V is in cubic meters and the sound absorption A is in square meters. Constant $k = 0.049$ s/ft when volume V is in cubic feet and sound absorption A is in square feet.

Next, the total sound absorption is broken down into the sum of the products of the surface area S_i of each such sound-absorbing surface and the sound absorption coefficient α_i for this surface. That is, the total sound absorption A is given by the summation over all treated surfaces as expressed by the following relation:

$$A = \alpha_1 S_1 + \alpha_2 S_2 + \alpha_3 S_3 + \dots + \alpha_i S_i + A_R \quad (C.2)$$

where A_R is the residual sound absorption. A default value of A_R equal to 15% of the floor area accounts for the acoustically untreated room surfaces (for example, the untreated walls, ceiling, and bare, uncarpeted floor) and for the furnishings (for example, tables, chairs, and shelves (see C3.5)). For a carpeted room, a value for A_R of 20% of the floor area is recommended as a conservative default design value.

Alternatively, the designer can set A_R equal to 13% of the floor area plus the product of the carpet surface area and its sound absorption coefficient. The latter may vary from a minimum of less than 0.1 at 500 Hz to as high as 0.65 at 2000 Hz, depending on the type and thickness of the carpet and its underlayment. Many references, such as those listed in the bibliography to this annex, provide tables of sound absorption coefficients for different acoustical materials, including carpet, at different frequencies.

These same references may be used to provide alternative sound absorption coefficients for other surfaces in place of the preceding default assumptions. Tabulations of the sound absorption per table or chair are available from these references. Their values may be used if these furnishings are comparable to those intended for the learning space.

For best accuracy in calculations of reverberation time, it is recommended that laboratory-certified sound absorption coefficients be used. These are normally available from acoustical material manufacturers, (see C2.1).

Next, the values of α_i and S_i for the proposed materials and surface areas are substituted into equa-

tion (C.2). If necessary, the choices of material and material areas are adjusted until equation (C.1) is satisfied. The minimum total sound absorption is calculated from application of equation (C.1) for frequencies of 500 Hz, 1000 Hz, and 2000 Hz.

The process described above can be simplified substantially when only one type of sound-absorbing material is to be installed and A_R is assumed to be 15% of the floor area.

The volume V of the learning space can be expressed as the product of floor area S_f and average ceiling height H . Using equations (C.1) and (C.2) and a residual absorption of 15% of the uncarpeted floor area, it is straightforward to construct a table of the minimum required surface area S_1 as a percentage of the floor area for maximum reverberation times of 0.6 s and 0.7 s from table 1. The variables in the table are the sound absorption coefficient α_1 of the acoustical treatment and average ceiling height H .

With the assumptions described above, the entries in table C.1 for the minimum surface area of acoustical treatment S_1 as a percentage of floor area S_f were calculated from the following expression.

$$100(S_1/S_f) \geq 100\{[(kHT_{60}) - 0.15]/\alpha_1\} \quad (C.3)$$

where k is the constant employed in equation (C.1).

As shown in table C.1, for either of the two reverberation times, the required minimum surface area of acoustical treatment increases as the ceiling height increases and as the sound absorption coefficient decreases. The table shows the need to apply acoustical treatment to the walls as well as the ceiling for rooms with high ceilings and low sound absorption coefficients. Two examples illustrate application of the data in the table.

Example 1.

A rectangular core learning space has dimensions of 40 ft long by 25 ft wide by 9 ft high. It is planned to install sound-absorbing material only on the ceiling. The enclosed volume is $(40 \times 25 \times 9) = 9000$ ft³. From table 1, for this enclosed volume, the maximum reverberation time is 0.6 s at each of the three specified frequencies. Manufacturer's data indicate that the proposed acoustical ceiling material has sound absorption coefficients of 0.65, 0.80, and 0.90 at 500 Hz, 1000 Hz, and 2000 Hz, respectively.

From table C.1, for the smallest absorption coefficient of 0.65 and the 9 ft ceiling height, the required minimum area of treatment is 90% of the floor area of $40 \times 25 = 1000 \text{ ft}^2$, or 900 ft^2 . This leaves 10% of the ceiling area free for lighting and other services. If the allowance for lighting area is inadequate, some acoustical treatment may have to be installed on the walls.

NOTE 1. While the required sound absorption should be confirmed at each of the three frequencies, it will generally be found that conformance to the reverberation-time requirement of table 1 at 500 Hz will also ensure conformance at the two higher frequencies.

NOTE 2. If the manufacturer's sound absorption data are between the sound absorption coefficients listed in the first column of table C.1, the required treatment area can be computed by interpolation in the table. For example, if the lowest sound absorption coefficient for example 1 were 0.67 instead of 0.65, the relative treatment area for the ceiling would be $90\% \times (0.65/0.67)$ or 87% of the floor area or 870 ft^2 instead of 900 ft^2 .

A similar table can be constructed from equation (C.3) for a carpeted floor by changing the default value for A_R/S_f from 0.15 for uncarpeted floors to 0.2 for carpeted floors.

Example 2.

For the same core learning space as in example 1, it is now considered necessary to improve the intelligibility of speech in this lecture-type classroom. In accordance with the guidance in C3.1.2, additional sound-absorbing material is to be installed as a ring around the walls near the ceiling. The sound-absorbing ceiling treatment is to be of the same material as for example 1, but the proposed acoustical wall treatment has manufacturer-stated absorption coefficients of 0.45, 0.60, and 0.70 at 500 Hz, 1000 Hz, and 2000 Hz, respectively.

In this case, as a working assumption, assume that the ceiling is to provide 60% of the total sound absorption while the remaining 40% of the total sound absorption is provided by the wall treatment.

Therefore, the ceiling treatment area should be 60% of the 900 ft^2 determined for example 1 or $0.6 \times 900 = 540 \text{ ft}^2$. According to table C.1, for the 9 ft ceiling and the smallest sound absorption coefficient of 0.45 for the wall treatment, the minimum required surface area of wall-treatment material would be 130% of the floor area of 1000 ft^2 if it

were the only material used. However, under the assumptions, only 40% of that area is required or $0.4 \times 1.3 \times 1000 = 520 \text{ ft}^2$. For the room perimeter of 130 ft, the height of the wall treatment would need to be 4 ft on each of the four walls or 44% of the total wall area.

In summary, 540 ft^2 of ceiling treatment material and 520 ft^2 of wall treatment material would be required for the core learning space to conform to the 0.6 s reverberation time limit in table 1 while providing good intelligibility of spoken words. Other distributions of ceiling and wall treatment areas could be evaluated if it were considered that too much of the available wall area was devoted to sound-absorbing material.

C2.1 Sound absorption coefficients and related design considerations

The sound absorption coefficients for all acoustical materials supplied for the project should be determined in accordance with ASTM C423 [C2]. The learning facility owner's representative should request from the acoustical materials contractor(s):

- a) appropriate certification that all material(s) have been tested in full accordance with ASTM C423 and
- b) a table of the laboratory-certified sound absorption coefficients at 500, 1000 and 2000 Hz for the materials employed (see E4.2.1 in annex E). The mounting condition employed for these tests should be identified and, preferably, should be the same as the as-installed mounting configuration. The designer should recognize that when the cavity depth behind the acoustical material in a laboratory configuration mounting is greater than for the as-installed depth, the installed low-frequency sound absorption coefficients are usually lower than those for the laboratory tests.

Tradeoffs between the sound-absorption coefficients and the surface areas of treatment are allowed if the tradeoffs result in the same or lower reverberation times than those specified in table 1 for each of the three frequencies.

When selecting acoustical materials to meet the reverberation time performance criteria in table 1, it is prudent to allow for sufficient surface area coverage using sound absorption coefficients that fall in the lower range that alternative suppliers may provide. This procedure helps insure that the properly certified material from the lowest bidder is adequate.

Table C.1 — Minimum surface area of acoustical treatment for different sound absorption coefficients, ceiling heights, and reverberation times.

		(a) Reverberation time, T_{60} , of 0.6 s Ceiling height, H , ft								
Sound absorption coefficient, α_1	8	9	10	11	12	13	14	15	16	
	Ceiling height, H , m									
	2.44	2.74	3.05	3.35	3.66	3.96	4.27	4.57	4.88	
Minimum area of sound-absorbing material as a percentage of the floor area										
0.45	112	130	148	167	185	203	221	239	257	
0.50	101	117	134	150	166	183	199	215	232	
0.55	92	107	121	136	151	166	181	196	211	
0.60	84	98	111	125	139	152	166	179	193	
0.65	78	90	103	115	128	141	153	166	178	
0.70	72	84	95	107	119	130	142	154	166	
0.75	67	78	89	100	111	122	133	144	154	
0.80	63	73	83	94	104	114	124	135	145	
0.85	59	69	79	88	98	107	117	127	136	
0.90	56	65	74	83	92	101	111	120	129	
0.95	53	62	70	79	88	98	105	113	116	
1.00	50	59	67	75	83	91	100	108	116	

NOTE Sound absorption coefficients stated by a manufacturer to be greater than 1.0 based on laboratory tests may be taken as equal to 1.00 for purposes of this annex.

		(b) Reverberation time, T_{60} , of 0.7 s Ceiling height, H , ft								
Sound absorption coefficient, α_1	8	9	10	11	12	13	14	15	16	
	Ceiling height, H , m									
	2.44	2.74	3.05	3.35	3.66	3.96	4.27	4.57	4.88	
Minimum area of sound-absorbing material as a percentage of the floor area										
0.45	91	107	122	138	154	169	185	200	216	
0.50	82	96	110	124	138	152	166	180	194	
0.55	75	87	100	113	126	138	151	164	177	
0.60	68	80	92	104	115	127	139	150	162	
0.65	63	74	85	96	106	117	128	139	149	
0.70	59	69	79	89	99	109	119	129	139	
0.75	55	64	73	83	92	102	111	120	130	
0.80	51	60	69	78	86	95	104	113	121	
0.85	48	57	65	73	81	90	98	106	114	
0.90	46	53	61	69	77	85	92	100	108	
0.95	43	51	58	65	73	80	88	95	102	
1.00	41	48	55	62	69	76	83	90	97	

NOTE Sound absorption coefficients stated by a manufacturer to be greater than 1.0 based on laboratory tests may be taken as equal to 1.00 for purposes of this annex.

C3 Further design guidance

C3.1 Location of the absorbing material

C3.1.1 General Classrooms. In cases where there is no fixed lecture position for the teacher, and when ceiling heights are less than about 3 m (10 ft), the best option is to place most if not all of the sound-absorbing material on the ceiling. For ceiling heights greater than 3 m (10 ft), which is discouraged for classrooms, an increasing amount of the sound-absorbing material will have to be on the walls as the wall height increases above 3 m. If nearly all of the installed sound-absorbing material is on the ceiling, then it is prudent to introduce furnishings such as bookshelves of adequate height to assure that sound waves traveling across the room are scattered in the direction of the sound-absorbing acoustical ceiling.

C3.1.2 Lecture-type classrooms. Speech intelligibility studies [C3] have shown that, for lecture-type classrooms, it is best to ring the upper wall and ceiling with sound-absorbing material. This configuration enhances reflections to and from the back of the room, as well as back and forth across the room, thus promoting good speech communication between teacher and student and vice versa, as well as among students. This arrangement also enhances better communication for group discussions and pod formats where the teacher moves around the room.

For classrooms that have a relatively fixed teacher position, the sound-absorbing material should not be placed just above and in front of the teacher's position because that position would reduce the level of the teacher's voice at the positions of the students.

C3.2 Mounting of acoustical treatment in classrooms

Ceiling acoustical treatment is normally suspended from the ceiling with an air space specified by the architect. The height of the air space may, or may not, be the same as the 40 cm (16 inch) air space commonly used by manufacturers to achieve the sound absorption coefficients that are measured by a testing laboratory. As long as the minimum air space required for installing a lay-in ceiling exists, the actual sound absorption at frequencies of 500 Hz and higher should be not less than the published values. Experienced professionals should be consulted when reverberation at frequencies less than 500 Hz is a major concern.

Wall-mounted materials should be installed, as recommended by the manufacturer, with clips or glue to the wall surface or be fastened to added spacers to achieve the stated sound absorption coefficients.

C3.3 Reverberation control for ancillary and large core learning spaces

For ancillary spaces, such as corridors, gymnasias, cafeterias and large core learning spaces [volume > 566 m³ (> 20 000 ft³)] sound-absorbing material should be installed to reduce noise caused by the activities of occupants, as well as to control reverberation. The amount of acoustical treatment will vary widely, but corridors should generally have a total surface area of sound-absorbing material that is not less than 50% of the ceiling area and up to 75% if possible; 75% treatment area is recommended for corridors with high traffic or noisy lockers.

A measure of the sound absorption coefficient of acoustical materials is provided by a single number rating called the noise reduction coefficient (NRC), [C4, C5]. For cafeterias and for large core learning spaces with ceiling heights up to 3.7 m (12 ft), a suspended ceiling with an NRC of 0.70 or higher should be used for the full ceiling area exclusive of the area required for lights and ventilation grilles. Higher NRC ratings should be considered especially for ceiling heights less than 3.7 m. When the ceiling height is greater than 3.7 m (12 ft), especially if greater than 4.6 m (15 ft), a more detailed analysis by experienced personnel may be required to provide adequate control of reverberation. In any event, as suggested by table C.1, wall treatment should be included for such high-ceiling rooms. Depending on the amount of wall treatment, the ceiling NRC or treated area might then be reduced when some of the wall area is covered by sound-absorbing material. When permitted within sanitation restrictions, similar acoustical treatment should be employed in food-serving and food-preparation areas.

NOTE The Noise Reduction Coefficient is equal to the arithmetic mean of the sound absorption coefficients at 250, 500, 1000, and 2000 Hz, rounded to the nearest multiple of 0.05. The NRC of acoustical material should not be used for design or calculation of reverberation time for core learning spaces for purposes of this standard.

For rooms with high ceilings, such as gymnasias, the installation of acoustical treatment on the walls

is important to minimize reverberant build-up of noise level. Absence of any acoustical treatment on the walls of high-ceiling rooms can make the material on the ceiling less effective than expected.

Guidance is available in the references listed in the bibliography in C5 for many other architectural acoustics design objectives applicable to reverberation control in ancillary spaces and large core learning spaces. These objectives include but are not limited to:

- providing suitable reverberation times for large core learning spaces and dual-purpose ancillary spaces such as a cafeteria also used as an auditorium (e.g. - Ref. C5, C6, or C7), and
- including additional sound-absorbing material on the walls in corridors connecting noisy rooms to quieter areas of the school and in corridors with busy foot traffic or noisy lockers.

C3.4 Carpeting in classrooms

Carpeting in a classroom (for example, in an area where young children sit on the floor together for a story) can help substantially to reduce background noise in the classroom from chair and foot impacts or scuffing. Carpeting can also attenuate the transmission of this impact noise to the room below. The alternative use of neoprene chair leg tips should be considered as a way to help minimize chair-shuffling noise without the use of carpeting. See annex F for discussion of indoor air quality (IAQ) and multiple chemical sensitivity (MCS) issues for carpeting.

Carpeting alone usually does not provide enough sound absorption for classrooms since it is generally poor at low frequencies, even when newly installed. (See text following Equation C.2 for further details.)

C3.5 Absorption of furnishings and occupants

Calculations of reverberation times for learning spaces assume typical furnishings such as chairs, tables, and storage cabinets. A sound absorption equal to 5% of the floor area, already included in the residual absorption term A_R in equation C.2, is a conservative approximation for the sound absorption of these furnishings. These furnishings are normally floor-mounted and thus their quantity and hence their sound absorption will tend to be proportional to the floor area. The 5% figure is con-

sistent with limited experimental data comparing the reverberation for furnished and unfurnished classrooms.

The sound absorption of learning space occupants was considered in setting the limits on reverberation time in table 1 and should not be included in any calculations for the reverberation time of an unoccupied space. The sound absorption provided by an occupant is approximately equal to 0.55 m^2 (6.0 ft^2) for an adult student and about 20% less for a high school student and 40% less for an elementary grade student [C4].

C4 Guidelines for good acoustics in large classrooms and lecture rooms

This standard does not specify performance criteria or design requirements for enclosed learning spaces larger than 566 m^3 ($20\,000 \text{ ft}^3$). However, limited additional recommendations and design guidelines for larger rooms and other spaces in educational facilities, aside from those in C3.3, are given in this subclause.

Large lecture rooms generally differ physically and functionally in many ways from classrooms found in elementary and secondary schools. The teacher-student configuration tends to be fixed; the size of the room can vary greatly, sometimes accommodating hundreds of students. The shape of the room may vary from a traditional rectangular shape; HVAC systems usually have much greater capacities; and speech reinforcement systems as well as other fixed audiovisual facilities are common in such spaces.

For unamplified speech, beneficial sound-reflecting surfaces, especially over the teacher-lecturer, are necessary to assure adequate speech sound levels in the back of the room with relatively uniform distribution of the sound of spoken words. If the teacher-student configuration is fixed, beneficial reflections can be obtained with sound-reflecting surfaces placed above the lecturer, sometimes extending over the audience, on the ceiling, or sidewalls. Because of the larger room volumes, reverberation times usually are greater than in small classrooms, with values of 0.7 s to 1.1 s in occupied rooms not uncommon. To assure less variability in the reverberation time with changes in occupancy, it is always desirable to have sound-absorbing upholstered chairs in small auditoria. To minimize echoes, the back wall is often made sound absorbing, or is tilted to avoid sending reflections back toward the source, or both.

Because of the complexity of the design of large lecture rooms, experienced professionals should be consulted to ensure that the design and its implementation achieve the acoustical objectives of this standard.

Further guidance for detailed design considerations of lecture rooms can be found in a number of sources including [C1, C4-C11] listed in the bibliography.

Annex D (Informative)

Design guidelines for noise isolation

D1 Introduction

This annex provides informative design guidelines for noise isolation between learning spaces and between a learning space and other interior or exterior spaces. Application of these design guidelines will assist, but not guarantee, achieving conformance to the background noise level limits in table 1. The STC and IIC ratings in 4.5 are intended to provide a practical means of achieving this conformance. All acoustical aspects of the design and construction should therefore be consistent with this intent. In support of this intent, since many finished component assemblies involve the work of more than one building trade, architectural specifications should refer to noise control and isolation measures in all applicable sections. After completion of construction, on-site testing may

also be needed when it is necessary to verify conformance to the STC or IIC ratings of 4.5, (see E5.1 in annex E).

The noise isolation provided by wall or ceiling elements depends on both the materials used and the installation practices and may be strongly affected by sound leakage at joints and penetrations and unintended flanking paths around these elements. When a high degree of noise isolation is required, as for music rooms, flanking of sound transmission through common floors, walls, and ceilings can limit the isolation actually achieved unless proper steps are taken in the design and construction.

The noise isolation requirements of this standard are similar in concept to requirements incorporated in several existing national and international building codes. Examples include: a) Appendix Chapter 12 Division II-Sound Transmission Con-

trol of the 1997 Uniform Building Code (UBC), b) Section 1206 of the 2000 International Building Code, and c) Standard SSTD 8-87 of Southern Building Code Conference International (SBCCI). All of these prescribe minimum STC ratings for separating walls and floor-ceiling assemblies. Except for the SBCCI code, they also prescribe minimum IIC ratings for floor-ceiling assemblies. The requirements for this standard differ from those in the above codes because the application for the space is different and, in many cases, have more stringent acoustical design requirements.

D2 Noise isolation

D2.1 Noise isolation between interior spaces

Table 2 specifies the required minimum STC ratings for interior and exterior walls surrounding enclosed learning spaces. The table presents design requirements for STC ratings of typical wall constructions where the wall is continuous to the floor below or floor-ceiling system above, with all penetrations adequately sealed, (see the guidance in ASTM E497 [D1]). General design guidance on noise isolation is provided in many texts and reports on building noise control including references D2 to D15.

D2.2 Noise isolation of open-plan classrooms

The low noise isolation that is inherent with open-plan classrooms is generally well below the design requirements in table 2. Therefore, this standard emphasizes that open-plan classroom design should be strongly discouraged since the resulting background noise levels in a core learning space as a result of activities by students in other core learning spaces within an open classroom setting are highly likely to exceed the background noise limits in table 1. The poor acoustical performance of open-plan systems has a negative impact on the learning process and tends to defeat any teaching methodology advantages that may accrue from their use.

D2.3 Outdoor-to-indoor noise isolation

D2.3.1 Outdoor-to-noise environments. There is no single answer for the proper amount of noise isolation to include in the design to shield a learning space from industrial or transportation outdoor noise sources. Each situation is unique with regard to distance to, and the extent and characteristics of, industrial sources, local traffic, or other transportation noise sources. The best solution to out-

door-to-indoor noise isolation design is to measure the current, or predict the future, noise levels of external sources at the proposed locations for facades. The next step is to determine the necessary outdoor-to-indoor noise level reduction to achieve the required interior background noise level in table 1. (See D2.3.3 for one approximate method.) It is good design practice to allow a margin of safety to account for uncertainties, including the possibility that current outdoor sound levels may increase in the future. For predictions of external noise levels, widely accepted models for assessing industrial or transportation noise sources will normally be available to environmental planners or acoustical consultants. For some sites, maps or contours of the current or projected outdoor noise environment may be available from local planning departments.

Selection of materials and acoustical design for the exterior envelope of a school building should consider these measured or predicted noise levels. Knowledge of these levels can assist in achieving adequate acoustical design features to attenuate the outdoor noise levels and ensure that the interior background levels do not exceed the limits in table 1.

D2.3.2 Selecting sites for learning facilities. As recommended by ANSI S12.9/Part 5 [D10], learning facilities should not be located at sites where the yearly average day-night average sound level exceeds the following limits with corresponding construction methods:

- 60 dB to 65 dB for conventional construction methods for the learning facility, providing the external walls are designed to a minimum STC rating of 50 consistent with the minimum ratings in table 2 and table 3;
- 65 dB to 75 dB if the external shell of the learning facility is designed to provide adequate noise isolation in order to conform to the limits in table 1 for background noise levels (see D2.3.3).

Under no conditions should a new learning facility be located at a site where the yearly average day-night average sound level exceeds, or is predicted to exceed, 75 dB.

D2.3.3 Approximate STC ratings to achieve a desired outdoor-to-indoor noise level reduction. Given the limits on background noise levels from table 1 and the external noise environments established by one of the procedures outlined in

Table D.1 — Approximate difference between the minimum STC rating required for building envelope components and the required outdoor-to-indoor noise level reduction

Fenestration %	(STC rating of walls and roofs) minus (outdoor-to-indoor noise level reduction) dB	(STC rating of doors and windows) minus (outdoor-to-indoor noise level reduction) dB
1 to 25	15	6
26 to 70	20	11

NOTES

- a) Fenestration is the percentage of the total wall and roof surface area that consists of windows, doors, and other openings. For rooms without a roof, it is the percentage of the total wall area made up of windows, doors, and other openings.
- b) The values for the nominal STC rating minus the outdoor-indoor noise level reduction in columns 2 and 3 are based on the expectation that the dominant outdoor noise source is vehicular traffic. If other sources dominate, adjustments may be needed. For example, if aircraft noise is the dominant source, the minimum required STC rating may increase by about 2 dB.

D2.3.1 and D2.3.2, the recommended STC rating for the wall, roof, door, and window elements of the school building envelope may be estimated from the data in table D.1.

Table D.1 gives the approximate difference in decibels between the minimum STC rating of the exterior elements of a learning space and the required outdoor-to-indoor noise level reduction for two ranges of the relative area of the fenestration in the envelope. While only an approximation, the data in the table may be used for initial estimates of the STC rating required for the components of the exterior envelope of the structure.

NOTE Outdoor-to-indoor noise level reduction is the difference in A-weighted sound level between a specified outdoor sound field and the resulting A-weighted sound level in the room abutting the facade or facade element of interest. It can be measured in accordance with ASTM E966 [D9] where it is called "outdoor-indoor level reduction".

As an example, assume that the dominant source of exterior noise is road traffic and that the maximum one-hour-average A-weighted noise level is 65 dB at the nearest exterior classroom wall facing the traffic. To conform to the background noise limit inside the classroom of 35 dB from table 1, the nominal outdoor-to-indoor noise level reduction would have to be 65 – 35 or 30 dB. According to table D.1, for an exterior wall with fenestration greater than 25%, the nominal STC rating of the

exterior walls would have to be at least 30 + 20 or 50. The STC rating of the windows would have to be at least 30 + 11 or 41.

To obtain estimates of the required STC ratings that are better than those obtained from application of table D.1 would require an assessment of the frequency spectrum of the long-term average exterior noise level. Also needed is the frequency-dependent sound transmission through the walls, roof, windows, and doors that are planned for the envelope of the school building (see ref. D8, D9).

D2.4 STC ratings for composite elements of a wall or roof assembly

STC ratings for a composite of several elements in a structural assembly may be estimated by application of the data in table D.2. Table D.2 may be employed to determine the STC rating of two different building elements such as walls, doors and windows with STC ratings, STC (1) and STC (2), where STC (1) is greater than STC (2) and with corresponding surface areas S1 and S2.

Enter table D.2 in the column across the top with the difference in the STC ratings rounded to the nearest 3 dB. Then go down to the row indicated in the left-most column to the range that includes the area S2 as a percentage of the total area (S1 + S2) of both elements. At the intersection of the row and column, find the correction to subtract from

Table D.2 — Correction data for estimating the STC rating of a two-element composite building assembly.

S2/(S1+S2) × 100%	STC (1) rating minus STC (2) rating, dB									
	3	6	9	12	15	18	21	24	27	30
0 to 0.2	0	0	0	0	0	0	0	1	2	3
>0.2 to 0.5	0	0	0	0	0	1	1	3	4	6
>0.5 to 1	0	0	0	0	1	2	3	4	7	9
>1 to 2	0	0	0	1	2	3	4	7	9	12
>2 to 5	0	0	1	2	3	5	7	10	12	15
>5 to 10	0	1	2	3	5	7	10	13	16	19
>10 to 20	1	2	3	5	7	10	13	16	19	20
>20 to 30	1	2	4	7	9	12	15	18	21	24
>30 to 40	1	3	5	8	11	14	17	20	23	26
>40 to 60	2	4	7	9	12	15	18	21	24	27
>60 to 80	2	5	8	10	13	16	19	22	25	28
>80 to 100	3	6	9	12	15	18	21	24	27	30

STC (1) to yield the estimate for the STC rating of the composite assembly. For more than two elements in a composite assembly, repeat the process by combining the STC of the composite assembly consisting of the first two elements with the STC of the third element, and so on.

As stated in NOTE a) to tables 2 and 3, the STC rating for the walls of a corridor, office, or conference room containing entrance doors excludes these entrance doors. The design and anticipated STC rating for such entrance doors is given in 4.5.5.

D2.5 Isolation from impact noise or vibrating machinery

D2.5.1 Design guideline for impact noise isolation for floor-ceiling assemblies. For learning spaces in multi-story school buildings, classrooms in lower stories may need to be protected from the noise of impacts on the floor of rooms immediately above. Impact noise may arise from footfalls or the scuffing of furniture in the room above. Impact noise can be reduced sufficiently by ensuring that the floor-ceiling system has an adequately high Impact Insulation Class (IIC) rating. Installing carpet on the floor will almost always ensure an IIC rating greater than 50 but may not reduce the low-frequency impact sounds sufficiently. It is good practice to design the floor-ceiling assemblies to achieve a minimum IIC 50 rating without carpeting above classrooms or other core learning spaces. For this purpose a permanent resilient underlayment may be required to isolate the finished floor from the structural floor system.

To achieve high IIC ratings, it may be necessary to isolate the ceiling from the floor above. This can be accomplished by suspending the ceiling with resilient channels or isolation hangers. Good architectural practices, including careful isolation design and attention to detail in construction, are important to ensure the realization of high IIC ratings. References D8 and D11 to D15 in the bibliography provide extensive IIC test data. Product manufacturers can be consulted for additional data.

D2.5.2 Design guideline for noise isolation from vibrating machinery. Vibration isolation methods, such as rubber pads or spring systems under the mounting points, should always be employed under rotating machinery to isolate it from floor-ceiling systems and prevent structurally-transmitted sound from entering learning spaces. This isolation is particularly important for roof-mounted rotating machinery where the deflection of the roof has to be considered in vibration isolation design. Design methods for such vibration isolation are documented in widely available noise control handbooks, (See ref. D2, D8 and D15 in the bibliography).

Annex E (Normative)

"Good architectural practices" and procedures to verify conformance to this standard

E1 Introduction

This annex provides recommendations in clause E2 for "good architectural practices" that will help to achieve the objectives of this standard. Clauses E3, E4, and E5 describe procedures that shall be followed to verify conformance to the requirements and recommendations of this standard, in the event that such verification is required. If verification of conformance is not required, the procedures described in clauses E3, E4, and E5 are provided for information only and the entire annex then shall be considered to be informative rather than normative.

This standard covers a range of requirements, some of which are relatively simple to accommo-

date by following the design guidelines given in other annexes. However, concerns about the actual acoustical environment of learning spaces may arise depending on a combination of factors such as building siting, variability in the installation of the HVAC system, and variability in the details of the construction techniques. For these and other reasons, verification tests may be necessary to evaluate conformance to the requirements of this standard.

Nonconformance to the provisions of this standard may be suspected when subjective evaluation of a learning space under typical use indicates excessive background noise, reverberation, insufficient noise isolation, or poor speech intelligibility.

Verification tests and analyses, if required, should be performed by qualified personnel (see B6 in annex B).

E2 "Good architectural practices" and acoustical performance considerations during and after construction

E2.1 Prior to completing construction

"Good architectural practices" during the design and construction of a new or renovated learning space include the following actions:

phase 1 – designing to conform to this standard (see annexes B, C, and D);

phase 2 – monitoring activities during construction to ensure that acoustically important design features are not compromised; and

phase 3 – checking for conformance to the principal requirements of this standard before completion of construction or renovation is accepted.

For a new or a renovated learning space, the architectural design in phase 1 should utilize the guidance provided in annexes B, C, and D. Because many structural component assemblies involve work by more than one building trade, the architect's specifications should cross-reference the noise control and noise isolation measures in all applicable sections of the specifications.

During construction phase 2, in addition to, and in advance of, conventional on-site inspections, special training should be provided to those in relevant building trades who will perform the work, or to their supervisors. The training should describe guidelines for implementing what often may be unconventional or unfamiliar construction methods. For example, representatives of certain building trades may not realize that inadvertent or careless disposal of debris or temporary bracing in the space between wall surfaces can cause a drastic reduction in noise isolation between adjacent learning spaces.

It is important to emphasize to those doing the work during the construction phase that all cracks or joints between wall segments or wall-floor or wall-ceiling joints should be sealed with a permanently flexible caulking compound. However, no attempt should be made to seal cracks or joints that are wider than 6 mm (0.25 in.). Solid filler, also caulked, with a surface weight density comparable to that of the material on each side of the crack should be used to seal cracks that are wider than

6 mm. ASTM C919 [E1] provides procedures for the use of sealants to maintain the design for noise isolation. The architectural design drawings should include a reference to ASTM C919 for sealing procedures.

To check conformance to the key requirements of this standard after construction is completed but before the learning space is occupied (phase 3), the following evaluations are recommended:

- 1) measure the background noise levels within learning spaces,
- 2) measure the noise isolation between them, and
- 3) calculate (or measure) reverberation times (see E3, E4, and E5 for procedures).

E2.2 After commissioning

After commissioning (accepting completion of construction), "good architectural practices" include:

- 1) being alert for, and monitoring of, degradation of acoustical materials, and
- 2) responding to complaints about the acoustical environment in a learning space.

Over time, some of the noise control features designed into a learning facility may degrade. One example of such degradation is changes in the balance, or fan operation, of the HVAC system leading to excessive low-frequency noise. Another example is the degradation of designed noise isolation provided by operable partitions as a result of wear and tear of floor and edge seals. A third example is painting of the sound-absorbing material on ceilings and walls.

Tests to verify conformance to this standard may be performed in response to complaints about the acoustical environment in the learning spaces. The results of these tests, and those performed prior to accepting completion of construction, will assist in analyzing the basis for any future complaints about the acoustical environment in the learning spaces.

E3 Verifying background noise levels

E3.1 Selecting learning space for measurements

Ordinarily, comprehensive testing is not required for all learning spaces in a given facility to which this standard applies and appropriate sampling procedures should be adequate. Selection of the size of the sample should consider the need to

evaluate spaces expected to have the highest levels of background noise because of their proximity to internal noise sources (e.g., mechanical equipment rooms) or their proximity to external noise sources (e.g., road traffic).

The test procedures in the balance of this clause apply to each learning space in which background noise levels are to be measured.

E3.2 Room conditions

Background noise levels shall be measured while adjacent spaces (for example, rooms and corridors beside, above, and below the space in which the measurements are to be made) are unoccupied. Students or school staff members, in the remainder of the facility, shall be requested to not carry out any activity that could increase the background noise level in the room under investigation.

Background noise levels shall be measured during an hour when the background noise levels are expected to be a maximum. Background noise levels shall be measured with the HVAC system and other building services at their appropriate maximum operational conditions as specified in 4.3.2. Lights shall be on; doors and windows shall be closed.

E3.2.1 Instructional equipment

Portable and permanent instructional equipment (for example, computers and audio-visual systems) shall be turned off to obtain background noise levels required by this standard.

However, it is strongly recommended that background noise levels also be measured according to the procedures in this annex when such instructional equipment and building services are operating simultaneously. When this total background noise level exceeds the limit in table 1 by more than 3 dB, steps should be taken to reduce the level of the noise produced by the instructional equipment.

E3.3 Room description

The overall dimensions of the learning space shall be measured and the enclosing volume calculated. The locations and dimensions of major features shall be noted on a diagram with plan and elevation views showing: 1) the location of HVAC components and other noise sources within the

space; 2) the position and dimensions of windows and doors; and 3) the heights and locations of partial height walls.

E3.4 Test instruments

Two types of instruments are required — a sound level meter and a compatible acoustical calibrator (or sound calibrator).

E3.4.1 Sound level meter. The sound level meter shall provide frequency weightings A and C, and SLOW time-weighting.

The sound level meter shall be an integrating-averaging type capable of measuring time-average sound levels or a conventional sound level meter capable of measuring SLOW time-weighted sound levels. An integrating-averaging meter is preferred.

An integrating-averaging sound level meter shall conform to the class 1-performance specifications of IEC 61672-1 [E2] or to the performance specifications of ANSI S1.43 [E3] for type 1 integrating-averaging sound level meters. A conventional sound level meter shall conform to the class 1 specifications of IEC 61672-1 or to the specifications of ANSI S1.4 [E4] for type 1 sound level meters. For either type of sound level meter, conformance to IEC 61672-1 is preferred.

To demonstrate conformance to the background noise limits of table 1, the maximum A-weighted level of self-generated noise of the sound level meter shall not exceed 30 dB for the model of microphone installed on the sound level meter.

NOTE Sound level meters designed in conformance with the above IEC or ANSI standards may have A-weighted self-noise levels greater than 30 dB. Conformance to these standards does not assure compliance with this required maximum self-noise level.

To carry out the preliminary survey of the background noise levels in the manner described in E3.7, a conventional sound level meter conforming to IEC 61672-1 class-2 or ANSI S1.4 type-2 specifications may be an acceptable alternative. To be acceptable, the lowest noise level measurable by the instrument shall be at least 5 dB below the actual measured background level. This ability may be demonstrated by observation in a very quiet location. Alternatively, the manufacturer may provide the lowest measurable level for this instrument.

E3.4.2 Acoustical calibrator. The acoustical calibrator shall conform to the requirements of IEC

60942 [E5] for a class 1 instrument or to the requirements of ANSI S1.40 [E6] for a type 1 instrument. Conformance to the standard corresponding to the sound level meter standard is preferred. The actual sound pressure level and nominal frequency of the calibration signal shall be known for the microphone installed on the sound level meter.

E3.5 Calibration

The sound level meter and the acoustical calibrator shall each have a certificate from a qualified acoustical testing laboratory indicating that a calibration of both instruments has been performed within the time interval recommended by the manufacturer but not more than 24 months prior to the date of the tests. The certificate shall apply for reference environmental conditions defined by the manufacturer. The calibration of the sound level meter and acoustical calibrator shall be checked periodically to ensure that measurements with the sound level meter are accurate.

Before initiating sound level measurements, the calibration of the sound level meter shall be verified in accordance with the procedure described in the Instruction Manual for the calibrator. Adjustments shall be made to the calibration in accordance with this manual to account for any significant difference between the prevailing atmospheric pressure and air temperature and the reference conditions (i.e. - 760 mm Hg, and 23 °C).

E3.6 Selecting measurement locations

The customary listening areas used for speech communication shall be determined for each learning space. The customary listening areas include the students' seating areas and the areas used by the teacher. These listening areas may be relatively fixed within a classroom or vary substantially, depending on the seating arrangement and teaching style. A maximum of six measurement locations shall be selected within the customary listening area and at distances not less than 1 m (40 in.) from a wall or other large solid surface, except for measurement locations close to the floor.

The location in the customary listening area that has the highest sound level shall be designated the "key location". This location shall be determined by observing the A-frequency-weighted and SLOW time-weighted sound level as the sound level meter is carried around the learning space with the room conditions as noted in E3.2. Sound

levels shall be noted at measurement heights representative of seated and standing students. Alternatively, this key location may be selected by listening at suitable positions near the apparent source of highest noise levels. If this subjective choice of the key location cannot be confirmed by the subsequent measurements of background noise, the background noise measurements shall be repeated using a correct key location. Before determining the other measurement locations it is prudent to evaluate preliminary survey results at the key location, as called for in E3.7.

A second location shall be on the opposite side of the listening area from the key location. Four other locations, two on each side of the listening area, shall be selected ahead and behind the key and second locations.

Three of the measurement heights above the floor, including that for the key location, shall be at the nominal ear elevation for students seated in a chair or on the floor. The other three heights shall be representative of the ear position of a standing student. The recommended approximate heights are shown in the following table.

Grade level	Approximate measurement height above the floor		
	Seated positions		Standing
	In a chair	On the floor	
K to 6	0.8 m (33 in.)	0.5 m (20 in.)	1.1 m (44 in.)
7 to 9	1.0 m (40 in.)	Not applicable	1.4 m (54 in.)
10 to 12 and adults	1.1 m (44 in.)	Not applicable	1.5 m (60 in.)

For learning spaces used by students of widely varying ages, at least four of the six measurement locations shall be those for the younger students.

Each measurement location shall be shown on a floor plan diagram and shall include the actual measurement heights employed.

E3.7 Measuring background noise

Following the initial survey described below, which can employ a hand-held sound level meter, the remainder of the background noise measurements should be conducted with the meter mounted on a tripod to minimize operator-induced noise and reflections from the operator's body. (A tripod may be

necessary for even the initial survey if the observed sound levels are very low). A large flat surface, such as a table or chair seat, shall not be used to support the instrument. To ensure that any air currents do not affect the reading of the sound level meter, and to protect the microphone from accidental damage, an appropriate microphone windscreen shall always be employed. The number of persons in the listening area shall be minimized, preferably with the test conductor the only person in the area.

The measurement of background noise shall begin with a preliminary survey to:

- 1) find the key location where the background noise level is the highest (see E3.6);
- 2) assess the likelihood that the background noise level conforms to the limits in table 1; and
- 3) determine if the background noise is steady or unsteady.

The sound level meter used for this preliminary survey may be an integrating-averaging type or a conventional type. In either case, it may be one that conforms only to the class-2 requirements of IEC 61672-1 or the type 2 requirements of ANSI S1.4 if the meter also conforms to the requirements in E3.4.1 for the lowest measurable level.

At the key location, the time-average A-weighted sound level shall be measured over each of five nominally consecutive 30-second intervals. The highest 30-second average, the lowest 30-second average and the total average of all five 30-second averages shall be noted. The same type of data shall be obtained for C-weighted sound levels. Each 30-second average may be obtained with an integrating-averaging meter set to a 30-second averaging period or, with a conventional sound meter, by visually observing the mean indication of the A-weighted and SLOW time-weighted sound level over the 30-second interval.

If the average background noise level from the above five A-weighted measurements is at least 3 dB more than the limits in table 1, then it may be concluded that the background noise levels in the room are not in conformance with the standard. No further background noise measurements are needed. If the average background noise level from the above five measurements is at least 3 dB less than the limits in table 1 and the background noise is judged steady as defined below, it may be concluded that the background noise levels in the room are in conformance with the standard. No

further A-weighted background noise measurements are needed.

If the average of the five 30-second samples falls within a 3 dB range above or below the limits of table 1, then confirmation of conformance or non-conformance to these limits shall be determined by additional tests carried out in accordance with one of the following procedures.

If the difference between the highest and the lowest noise levels of the five 30-second samples at the key location is not more than 3 dB, the background noise shall be judged steady and the measurement procedure in E3.7.1 shall be employed. If this difference is more than 3 dB, the background noise shall be judged unsteady and the measurement procedure of E3.7.2 shall be employed.

E3.7.1 Steady background noise. The one-hour-average steady background level for the typical usage hour may be obtained from measurements of one 30-second average sound level at each measurement location after ensuring that the room conditions are as specified in E3.2. Each 30-second average sound level may be measured in one of two ways and the results noted for each measurement location:

- 1) by use of an integrating-averaging sound level meter for a 30-second measurement interval or
- 2) by visual observation for 30 seconds of the mean sound level observed on a conventional sound level meter with SLOW time-weighting.

If any non-typical short-duration sound, such as a door slam, occurs during any measurement period, the measurement shall be stopped, the memory cleared if an integrating-averaging instrument is being used, and the 30-second measurement repeated.

The C-weighted sound level also shall be measured at the key measurement location applying the same process employed for the A-weighted sound levels. If the C-weighted sound level at this location exceeds the limit for A-weighted levels in table 1 by more than 18 dB, it is recommended that a more thorough evaluation be made of the C-weighted levels at other locations in the room to ensure conformance to 4.3.2.1.

E3.7.2 Unsteady background noise from transportation noise sources. For unsteady background noise, the measurement procedure of E3.7.1 (1) shall be followed, using an integrating-averaging sound level meter which, preferably,

can also determine the A-weighted SLOW time-weighted noise level exceeded for 10% of any measurement interval. The integration and averaging measurement interval shall be 60 minutes instead of 30 seconds.

During this measurement, the time of day and the apparent sources of significant transportation noise shall be identified and noted. Non-typical short-duration loud sounds that occur during the integration interval shall be noted, but the integration shall not be interrupted. Prior to reporting the one-hour-average sound level, the measured data may be processed to exclude such non-typical short-duration sounds.

The A-weighted, SLOW time-weighted noise level exceeded for 10% of the observation hour shall be noted directly if the sound level meter has this capability. Alternatively, manual data processing may be employed. For example, a record of 120 observations of 30-second samples of the A-weighted SLOW time-weighted noise level can be used to determine the level exceeded for 10% of the hour.

E3.7.3 Disturbing sounds from building services and utilities. If the presence of disturbing sounds (see 4.3.2.2) is suspected from building services and other utilities, a more thorough analysis of the acoustic environment may be required using appropriate signal analysis equipment familiar to an experienced observer.

E3.8 Verifying conformance to background noise limits

E3.8.1 Steady background noise. For the customary listening area in the learning space, conformance to the requirements of this standard is verified for steady background noise when the following conditions are satisfied.

- The 30-second-average A-weighted sound level at each measurement location does not exceed the corresponding limit specified in table 1, within the tolerance of 4.7 (1); and
- The 30-second-average C-weighted sound level at the key measurement location does not exceed the corresponding 30-second-average A-weighted sound level by more than the limit specified in 4.3.2.1.

E3.8.2 Unsteady background noise from transportation noise sources. Conformance is verified if the one-hour-average A-weighted sound level and the A-weighted, SLOW time-weighted

level exceeded 10% of the time do not exceed the limits specified in 4.3.1. The tolerance of 4.7 (1) applies separately and not cumulatively to each of these limits for the continuous test hour.

E4 Verifying reverberation times

E4.1 Methods

The preferred method to verify that the actual reverberation times do not exceed the maximum reverberation time specified in table 1 is to calculate the reverberation time at 500 Hz, 1000 Hz, and 2000 Hz. Alternatively, reverberation times may be measured directly. Reverberation times shall be measured when the calculated reverberation times exceed the limits from table 1, when the observed reverberation of the learning space appears to be excessive, or when significant differences are suspected between the assumed and the actual mounting conditions for the acoustic treatment.

If calculated and measured reverberation times differ by more than 0.1 s, the measured reverberation time shall take precedence. Results of calculations or measurements of reverberation times shall be rounded to the nearest 0.1 s and shall be within the tolerance limits of 4.7 (4) of the performance requirements in table 1.

E4.2 Reverberation time by calculation

The dimensions of the room shall be measured and the enclosing volume calculated. The dimensions of the sound-absorbing surfaces on the ceiling and walls shall be measured and the surface areas calculated for each different type of sound-absorbing surface.

The total sound-absorbing area in the room shall be determined by means of equation (C.2) in annex C with appropriate estimates for the sound absorption coefficients for the various sound-absorbing surfaces. A residual sound-absorbing area shall be computed according to C2.1 in annex C to account for absorption by furnishings and untreated surfaces. A default value for this residual absorption shall be 15% of the floor area for uncarpeted rooms or 20% for carpeted rooms. Sound absorption provided by occupants of the room shall be ignored. The reverberation time shall be calculated for each frequency by the Sabine equation (e.g. - see equation (C.1) in annex C).

E4.2.1 Sound absorption coefficients used for calculations. To calculate the reverberation time, best estimates of the sound absorption coefficients for the as-installed acoustic materials shall be used. These coefficients (see NOTE) shall be obtained from:

- a) the acoustical materials contractor, accompanied by the certification that they were obtained in accordance with ASTM C423 (see C2.1 in annex C) or,
- b) published results obtained in accordance with ASTM C423 for nominally identical materials and mounting configurations, (see bibliography)

If possible, allowance should be made for acoustically significant differences between the tested and as-installed mounting configuration.

NOTE Manufacturers do not commonly provide the octave band sound absorption coefficients needed for this standard. The values reported are usually those measured for one-third octave bands centered at these octave frequencies. If desired, sound absorption coefficients over the full octave band may be estimated by arithmetically averaging available one-third octave band values at 400, 500, and 630 Hz for the 500 Hz octave band, at 800, 1000 and 1250 Hz for the 1000 Hz octave band, and at 1650, 2000, and 2500 Hz for the 2000 Hz octave band.

When such reasonable data or estimates of the sound absorption coefficients are not available then verification of reverberation time shall only be done using the measurement method in E4.3.

E4.3 Reverberation time by measurement

Measurements of reverberation times shall be performed by, or under the supervision of, a person experienced in performing such measurements. The measurements shall follow procedures in conformance with, or equivalent to, those specified for field tests in ASTM E336 [E7] or in Appendix X2 of ASTM C423 [E8]. The recommended sound signal is random noise with a bandwidth extending at least from 315 Hz to 3150 Hz.

Reverberation times shall be measured at least at the key location noted in E3.6 for each learning space where reverberation times are to be measured.

Before measuring reverberation times, all HVAC fans and other noise-generating equipment, such as instructional equipment, should be turned off if

their noise prevents acquisition of valid measurements of reverberation times. All soft materials that are not a permanent part of the learning space (such as loose clothing and art supplies) shall be removed from the room. The learning space shall be otherwise furnished in the normal manner with chairs, tables, shelves, or cabinets. All windows, doors, and cabinets shall be closed. No more than two persons shall be present during the actual measurements.

No adjustments shall be made to any reverberation time measurements to account for the added absorption of any furnishings of any sort that were not present in the room at the time of the measurements.

E5 Verifying airborne and structureborne noise isolation

E5.1 Airborne noise isolation

When required, tests for conformance to airborne noise isolation requirements in table 2 shall be performed in accordance with the procedures of ASTM E336 [E7] and ASTM E413 [E9] for determining the Noise Isolation Class (NIC) as an approximation to the sound transmission class (STC) rating of a structural element. If there are no significant flanking sound-transmission paths and all sound leaks have been well sealed, the NIC rating is usually equal to, or slightly greater than, the STC rating determined by field tests for assemblies that separate two enclosed learning spaces.

The same ASTM test procedures also should be used to demonstrate conformance with the STC ratings recommended in table 3 for receiving ancillary learning spaces. All sound transmitted from the source room to the receiving room shall be considered to be transmitted through the separating partition. Engineering judgment shall be applied in the interpretation of measured NIC ratings; guidance for this judgment is provided in ASTM E336. The measured NIC ratings shall be within the tolerance limits of 4.7 (2) of the STC design requirements in table 2 and design recommendations in table 3.

E5.2 Structureborne (impact) noise isolation

When required, tests for conformance to structureborne or impact noise isolation requirements in 4.5.6 shall be performed in accordance with the testing procedures for determination of the Field Impact Insulation Class (FIIC) as defined in ASTM

E1007 [E10] for floor-ceiling assemblies separating occupied spaces from learning spaces below. All sound transmitted from the source room to the receiving room below shall be considered to be transmitted through the floor-ceiling assemblies.

E5.3 Sound leakage paths

Tests for airborne and structureborne noise isolation shall not be attempted until all sound leakage paths and gaps have been eliminated by caulking and sealing in accordance with the recommended practice in ASTM C919 [E1].

E6 Test report

A test report shall document the results of all tests or calculations carried out in conformance with the procedures of E3 to E5 of this annex. The report shall reference this standard and the applicable clauses of this annex. The report shall describe the instruments used and their dates of calibration when applicable. The report shall include tables of all measured data and the results of all analyses. Drawings shall be included to show the items noted in E3.3 and E3.6. To support validation of the reverberation time by calculations, the report shall also include the types, locations, and areas of permanently installed sound-absorbing material and their mounting methods.

The report shall state whether the learning space does or does not conform to the requirements of this standard and shall identify the applicable clause(s). If the space does not conform to the requirements of this standard, the report may include, if requested, recommendations for modifications to achieve compliance. These recommendations should be prepared or approved by a person experienced in the applicable acoustical technology.

The report shall name the persons performing the validation tests or calculations and the name of the person who prepared the report.

Annex F (Informative)

Potential conflicts between the acoustical requirements of this standard and indoor air quality (IAQ) and multiple chemical sensitivity (MCS)

F1 Introduction

Concerns about indoor air quality (IAQ) and multiple chemical sensitivity (MCS) issues have

caused some schools to remove all porous materials from the classrooms and, in some cases, from the ventilation supply ducts, thus potentially compromising the benefits for classrooms that used

the frequency spectrum of the noise - a refinement that is beyond the scope of this standard and is not recommended.

A-weighted and C-weighted sound levels are considered adequate descriptors for purposes of this standard to evaluate the acoustical environment in learning spaces. The difference, measured in 56 classrooms, between the A-weighted time-average sound level of steady background noise and the corresponding value of any of the three descriptors noted below varied from 2 dB to 24 dB depending on the location of the learning space in the U.S. and whether the HVAC system was operating. *Thus, none of these supplemental descriptors should be employed for judging conformance to this standard.*

G2 Noise Criteria Rating (NC)

The noise criteria (NC) rating, in common use by architects and consultants for acoustical room design, is based on contours of octave-band sound pressure levels of the background noise. It is thus a measure of the frequency spectrum of this noise and reflects the change in the sensitivity of human hearing as the background noise level changes [G1], especially at frequencies important for speech communication and for annoyance of low-frequency sound.

G3 Balanced Noise Criteria Rating (NCB)

The balanced noise criteria (NCB) rating [G2] are also based on similar contours of octave-band sound pressure levels. The contours for the NCB descriptor extend to lower frequencies than do the contours for the NC descriptor.

G4 Room Criteria Rating (RC)

The room criteria (RC) rating [G3] is recommended by ASHRAE for evaluating background noise from HVAC systems and other mechanical equipment by use of contours of octave-band sound pressure levels. These contours are similar to those for the NC and NCB descriptors but have lower allowable sound levels at very low and very high frequencies.

**STANDARDS SECRETARIAT
ACOUSTICAL SOCIETY OF AMERICA**

The Standards Publication Program of the Acoustical Society of America (ASA) is the responsibility of the ASA Committee on Standards (ASACOS) and the ASA Standards Secretariat, headed by its Standards Manager.

The Acoustical Society of America provides the Secretariat for four Accredited Standards Committees of the American National Standards Institute (ANSI): S1 on Acoustics, S2 on Mechanical Vibration and Shock, S3 on Bioacoustics, and S12 on Noise.

These four Accredited Standards Committees also provide the United States input to various international committees (IEC and ISO). Standards Committees S1 Acoustics and S3 Bioacoustics provide the United States input to ISO/TC 43 Acoustics, and IEC/TC 29 Electroacoustics, as the Technical Advisory Groups. S12 on Noise serves as the U.S. Technical Advisory Group for ISO/TC 43/SC1 Noise. S3 is the U.S. Technical Advisory Group for ISO/TC 108/SC4 Human Exposure to Mechanical Vibration and Shock. S2 serves as the U.S. Technical Advisory Group for ISO/TC 108, Mechanical Vibration and Shock; ISO/TC 108/SC1, Balancing, including Balancing Machines, ISO/TC 108/SC2 Measurement and Evaluation of Mechanical Vibration and Shock as Applied to Machines, Vehicles, and Structures; ISO/TC 108/SC3 Use and Calibration of Vibration and Shock Measuring Instruments; ISO/TC 108/SC5 Condition Monitoring and Diagnostics of Machines; and ISO/TC 108/SC6 Vibration and Shock Generating Systems.

ASACOS and the ASA Standards Secretariat provide the Secretariat for the U.S. Technical Advisory Groups listed above and administer the International Secretariat for ISO/TC 108 Mechanical Vibration and Shock, ISO/TC 108/SC1 Balancing, Including Balancing Machines, and ISO/TC 108/SC5 Condition Monitoring and Diagnostics of Machines.

Standards are produced in four broad areas: physical acoustics, mechanical vibration and shock, bioacoustics, and noise, and are reaffirmed or revised every five years. The latest information on current ANSI standards [including Nationally Adopted International Standards (NAIS Standards)], as well as those under preparation is available from the ASA Standards Secretariat. For information, please contact S. B. Blaeser, Standards Manager, Acoustical Society of America, 35 Pinelawn Road, Suite 114E Melville, NY 11747, USA. E-mail asastds@aip.org. Nonauditory Effects of Noise on Children: A Critical Review

Gary W. Evans
Cornell University
New York, USA

Stephen J. Lepore
Carnegie Mellon University
USA

Large numbers of children both in the United States and throughout the economically developing world are chronically exposed to high levels of ambient noise. Although a great deal is known about chronic noise exposures and hearing damage, much less is known about the nonauditory effects of chronic ambient noise exposure on children. To estimate the risk of ambient noise exposure to healthy human development, more information about and attention to nonauditory effects such as psychophysiological functioning, motivation, and cognitive processes is needed. This article critically reviews existing research on the nonauditory effects of noise on children; develops several preliminary models of how noise may adversely affect children; and advocates an ecological perspective for a future research agenda.

Keywords: noise, stress, nonauditory effects, health, cognitive

INTRODUCTION

In 1973 nearly 10 million American school children were exposed to ambient noise levels that exceed federal standards for hearing protection in work settings (Environmental Protection Agency, 1974). Recent studies estimate that American children on average are exposed daily to noise levels in the range of 76-80 Leq (unweighted average of decibel levels for 24 hours) (Roche et al., 1982; Schori & McGatha, 1978). To put these figures in perspective, the EPA recommended limit for risk to hearing is 70 Leq daily exposure for children. Since these assessments of childhood noise exposure, there have been marked increases worldwide in the number of children exposed to noise levels loud enough to impair hearing: this is especially true in underdeveloped countries (Evans, 1990; Suter, 1991).

Many *nonauditory* effects of noise on children also have been detected during the past two decades of research. Nonauditory effects of noise refer to impacts not directly related to sound-

induced damage to the auditory system. Nonauditory effects of noise, such as elevated sympathetic nervous system activity or disturbances in attentional processes, are apparent in children exposed to noise levels far below those necessary to induce auditory damage.

Although there is abundant evidence and analysis of the auditory effects of noise on children (Kryter, 1985; Mills, 1975), there has been little systematic, critical analysis of the nonauditory effects of noise exposure among children. This is a critical omission if we are interested in estimating the true risk of noise exposure to healthy human development. The present article critically examines the empirical evidence on the nonauditory effects of noise on children. The work is organized into three general areas of functioning: physiological, motivation, and cognitive. Both conceptual as well as methodological limitations in the extant research are examined.

Physiological Effects of Noise

Work in animal models and in various occupational settings suggests heightened activation of the cardiovascular system among organisms

Table 1. Effects of noise on cardiovascular outcomes

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Brackbill et al. (1982)	HR	1 h white noise for 4 consecutive days. 50 and 75 dBA.	(78 males) ages 1 mon. to 80 yrs.	In infants and 8-year olds, HR decreased as sound levels increased. No other main or interactive effects of noise.
Cohen et al. (1980)	BP	Aircraft. 95 dBA peak.	(262) grades 3-4.	Noisy-school children had higher SBP and DBP than quiet-school children.
Cohen et al. (1981)	BP	Aircraft. 95 dBA peak.	(163) grades 3-4, longitudinal sample.	In the longitudinal attrition sample, there were no effects of noise on BP.
Cohen et al. (1986)	BP	Aircraft. 16 dBA sound reduction in noise-abated classrooms.	(163) grades 3-4, longitudinal sample.	SBP marginally lower and DBP significantly lower in quiet- than noisy-school children. SBP and DBP marginally lower in quiet- than noise-abated school children. No BP differences in children in noisy vs. noise-abated school.
Cohen et al. (1986)	BP	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Noisy-school children had higher BP than quiet-school children if were enrolled for 2 yrs or less. No noise effects on children enrolled more than 2 yrs.
Karsdorf & Klappach (1968)	BP	Traffic and street. 63-84 phon.	(262) grades 7-10.	Children in quiet schools had normal BP; whereas those in moderately- to very-noisy schools had elevated BP, especially among older boys.
Ising et al. (1990)	BP	Low altitude military flights. 125 dBA peak/Leq 68 dBA.	(433) ages 10-13 yrs.	Noise-related increases in SBP and DBP for girls, but not boys. Noise-related HR deceleration in boys and girls, but deceleration only significant in boys.
Karagodina (1969)	BP	Aircraft. 112 dBA peak/Leq 58 dBA.	(unavailable) ages 9-13 yrs.	Noisy-school children had higher BP than quiet-school children.
Roche et al. (1982)	BP	Self-report of exposure to loud noise sources. 80- Leq.	(233) ages 12-14 yrs.	Self-reported noise exposure levels not associated with BP.

Note: HR = heart rate, BP = blood pressure, S = systolic, D = diastolic.

chronically exposed to noise (Kryter, 1985; Smith, in press). As shown in Table 1, several studies have also uncovered evidence of possible linkages between chronic noise exposure and elevated blood pressure among children.

With two exceptions, all of the studies shown in Table 1 report elevations of resting blood pressure among children chronically exposed to noise. The one experimental study (Brackbill et al., 1982) found habituation to noise, which is a well established psychophysiological finding with short-term noise exposures (Glass & Singer, 1972). The extent of blood pressure elevations found from chronic exposure are probably not clinically significant for children during their youth (Voors et al., 1976), but could portend elevations later in life that might be health damaging (Berenson, 1980). To our knowledge,

there have been no long-term follow up studies of children exposed to noise at an early developmental stage. We know essentially nothing about the long-term consequences of early noise exposure on developing cardiovascular systems.

Both of the studies in Table 1 that found nonsignificant correlations between noise exposure and chronic blood pressure levels have methodological limitations. Roche et al. (1982) relied on children's retrospective reports of exposure to noise events (e.g., motorcycle use) during the previous six months. No data were presented on the reliability or validity of these noise estimates. Furthermore, the children monitored did not live near especially high noise sources (e.g., airports). Instead exposure to point noise sources such as machinery was estimated. Finally, resting blood pressure was only estimated

with one reading. On the other hand, this is the only study to examine the association between typical, daily noise exposures and resting blood pressure among children. All other studies have assessed the association between chronic blood pressure and exposure to high noise sources such as airports, roads, or trains. Analyses of the health effects of typical noise exposure for children are needed but with more adequate measurements of both noise exposure and blood pressure.

The second study to find a nonsignificant association between chronic noise exposure and resting blood pressure levels was conducted with children exposed to high levels of noise from an airport. Cohen et al. (1981) found that a difference in blood pressure between children attending noisy versus quiet elementary schools in a cross-sectional analysis did not replicate when reassessed one year later. Attritional analyses suggested that the failed longitudinal replication was caused by emigration of the families of children in noisy areas with the highest levels of blood pressure. Among children attending quiet schools, on the other hand, there was no selective attrition related to blood pressure levels.

Unlike other studies listed in Table 1, the three studies by Cohen and colleagues (Cohen et al., 1980; 1981; 1986) include statistical controls (e.g., social class, education) to counter potential third variable explanations of the associations uncovered between noise exposure and chronic levels of blood pressure. However, none of the studies is prospective, nor do any show a dose response relation between noise and blood pressure. Furthermore, all of the extant studies have relied upon gross indices of noise exposure – typically peak readings measured at schools.

Noise in the fetal and neonatal environment may be particularly harmful to fetuses and newborns because they are in a period of great organismic plasticity. It is well established that environmental sounds and vibration influence physiological and behavioral responses in the fetus (Pikus, 1991). There are contradictory data on the relations between ambient noise exposure and birth weight (for reviews see Pikus, 1991; Smith, in press) but little or no definitive evidence for teratological effects of chronic noise exposure (Edmonds et al., 1979; Meyer et al., 1989). Nonetheless, it is critical for more thorough and extended investigation of the potential impacts of routine modern medical procedures such as ultrasound monitoring or

placement of premature babies in intensive care nurseries with extremely noisy equipment (Gottfried et al., 1981; Lawson et al., 1977).

Summary

Residing or attending school near a major noise source is associated with elevated blood pressure. More research is clearly called for, especially tracking children before, during, and after exposure to noisy environments. All evidence to date is correlational and even though some studies have included good controls, stronger, quasi-experimental designs are needed to firmly tie noise to the etiology of cardiovascular changes in children. The degree of blood pressure elevations is small, on the order of 4–8 mm of mercury, but these elevations do not appear to habituate with continued exposure (cf., Cohen et al., 1986). The clinical significance of such changes in childhood blood pressure is difficult to determine. The ranges of blood pressure among noise-exposed children are within normal levels and do not suggest hypertension. On the other hand, elevations in blood pressure among children appear to track into adulthood (Beren-son, 1980), increasing the potential risk for cardiovascular disease. It would also be of value to examine neuroendocrine makers of stress (e.g., cortisol) that have been implicated in the casual pathways between stressors and cardiovascular outcomes.

Emotional/Motivational Effects of Noise

The uncontrollability of chronic noise exposure may affect childrens' emotional and motivational states. When organisms are exposed to repeated, uncontrollable events, learned helplessness can occur (Abramson et al., 1978; Seligman, 1975). Learned helplessness means the organism learns that the outcomes of its behavior are independent of its responses. Learned helplessness is manifested as a lack of effort or responsiveness to environmental stimuli and challenges. Uncontrollable noise has been shown to induce helplessness in adults (Hiroto, 1974; Hiroto & Seligman, 1975; Krantz et al., 1974). Moreover, adults immediately following exposure to uncontrollable noise are less likely to persist on difficult or challenging aftereffect puzzles than their counterparts with prior exposure to controllable noise (Cohen, 1980; Glass & Singer, 1972).

Overall, though, very little is known about the

Table 2. Effects of noise on motivation (learned helplessness)

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Cohen et al. (1980)	Performance on moderately difficult puzzle after pretreatment with insoluble or soluble puzzle.	Aircraft. 95 dBA peak.	(262) grades 3-4.	Noisy-school children failed more on pretreatment soluble puzzle and difficult test puzzle, and were more likely to give up on difficult puzzle, than quiet-school children. There was a nonsignificant trend suggesting that longer exposure to a noisy school was associated with greater time to complete difficult puzzle.
Cohen et al. (1981)	Performance on moderately difficult puzzle.	Aircraft. 95 dBA peak.	(163) grades 3-4, longitudinal sample.	Noisy-school children were more likely to fail at the test puzzle and to take longer to solve the puzzle than quiet-school children. No noise effect on rate of giving up.
Cohen et al. (1981)	Performance on moderately difficult puzzle.	Aircraft. 16 dBA sound reduction in noise-abated classrooms.	(163) grades 3-4, longitudinal sample.	Sound attenuation improved children's performance on the original test puzzle.
Cohen et al. (1986)	Performance on moderately difficult puzzle.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Noisy-school children failed difficult puzzle more frequently than did quiet-school children.
Cohen et al. (1986)	Choice task.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Noisy-school children more likely than quiet-school children to give choice of reward to experimenter.
Moch-Sibony (1984)	Rosenzweig frustration tolerance test.	Aircraft. 29 vs 54 SIL.	(80) kindergarten.	Noise-related decreases in frustration tolerance.
Wachs (1987)	Observer ratings of mastery-oriented play behavior.	Ratings of noise: 1 = normal level voices in home for 15 min. period to 4 = noisy level voices in home for more than half 15 min. period.	(88) 12 mon.	Less mastery-oriented play behavior in noisier homes.

Note: SIL = speech interference level.

relations between chronic exposure to environmental stressors such as noise and the induction of helplessness in human beings. Community surveys of noise annoyance frequently note that while annoyance is common, complaints or other actions to intervene are rare (Evans & Tafalla, 1987). Most residents who are annoyed by noise report feeling unable or helpless to alter the situation (Jue et al., 1984). The small minority who do complain or take other actions report feeling greater self-efficacy to cope with the noise (Jue et al., 1984).

As shown in Table 2, a few studies have examined the effects of noise on children's motivational states. The significant relations between noise exposure and motivational deficits in one cross-sectional study (Cohen et al., 1980) were replicated both in a longitudinal study (Cohen et al., 1981) and in a second, cross-sectional study

(Cohen et al., 1986). Higher noise exposure in children has been associated with reduced persistence on challenging puzzles and greater abdication of choice over rewards (see Table 2). Perhaps the most persuasive data of reduced motivation in an achievement related situation is Cohen et al.'s (1980) findings on giving up. Not only were children from noisy schools less likely to solve a challenging puzzle within a four minute time period, a substantially greater proportion of them (15%) simply gave up before the allotted time had elapsed, often remarking that they couldn't do the task, in comparison to 2% of their quiet school counterparts who gave up.

Of additional interest, teachers from schools located in noisy settings report more difficulties motivating students to perform than do teachers from relatively quiet schools (Crook & Langdon, 1974; Kyzar, 1977; Moch-Sibony, 1984).

Even very young children appear to be less motivated to engage in object mastery or control over their environment, after prolonged exposure to noise. For example, 12-month-old infants living in noisier households tended to engage in less effective, mastery-oriented interactions with toys in their homes than did children from relatively quiet homes (Wachs, 1987).

Learned helplessness is more apt to occur when individuals make stable, personological attributions (e.g., ability) rather than ascribe global or temporary reasons (e.g., bad luck, poor effort) for their failures (Abramson et al., 1974; Silver et al., 1982). No research on noise and motivation has examined these underlying attributional processes. Future research should also directly manipulate contingencies in a task (e.g., provision of insoluble puzzles) and then examine differences in tendencies to become helpless along with attributional measures, as a function of chronic noise exposure. In addition, researchers should examine the possible mental health consequences of noise-related learned helplessness. If noise heightens vulnerability to helplessness, then it is reasonable to suspect possible connections between chronic noise exposure and certain psychological problems in children. In one exploratory study, Wachs (1988) found a positive association between noise levels in the home and adaptability, but noise was unrelated to several other indices of temperament. In another study, a composite index of noise and confusion/clutter in the home was linked to difficulty in care requirements for 18-month-old children, although not for 12-month or 24-month-olds (Wachs, 1989).

Summary

Brief exposures to uncontrollable noise are capable of inducing learned helplessness in adults. Chronic residential exposure to noise also appears to be associated with feelings of helplessness among adults living nearby airports. Although the evidence is scant, there are suggestive findings indicating that children chronically exposed to ambient noise sources may be more vulnerable to learned helplessness. Children attending schools in airport flight paths are less likely to solve or persist in attempting to solve challenging puzzles. They are also more likely to abdicate choice over a reward to an adult rather than exercising the choice option themselves. Teachers of children in noisy schools also report, on average, greater difficulties in

motivating children in their school work. Noise in the home may be associated with mastery motivation in very young children. In addition to the small number of studies, all of which are correlational, another drawback to this area of work has been a lack of systematic integration of more sophisticated developmental paradigms for the measurement of motivational deficits in children. The potential pathways among chronic noise exposure, helplessness, and psychological health warrant further research.

Cognitive Effects of Noise

Research on the cognitive effects of noise exposure on children has received the most attention from researchers. This area of research can be subdivided into three subtopics: (i) attention and perception, (ii) memory, and (iii) intellectual achievement.

Attention and perception

The cognitive ability to perceive order and contingency in the environment presumably depends on some modicum of sustained attention to event sequences as they unfold. The interruptive, distracting effects of high ambient noise levels might directly affect the young child's ability to sustain voluntary attention or to concentrate (Heft, 1985).

As shown in Table 3, studies by Karsdorf and Klappach (1968), Kyzar (1977) and by Moch-Sibony (1984) have revealed deficits in standardized measures of sustained attention among children chronically exposed to noise. The standardized tests involve searching for target geometric stimuli from among fields of similar objects. In addition, teachers report that children in noisy schools tend to have more difficulties in concentrating in comparison to children from relatively quieter schools (Crook & Langdon, 1974; Ko, 1979; Kryter, 1985; Kyzar, 1977).

Cognitive studies on children with variable exposures to chronic noise sources also indicate possible decrements in visual attention (see Table 3). Children from noisy homes took longer to locate target pictorial stimuli within an array of pictures than did children from relatively quiet homes (Heft, 1979). Children attending daycare centers located near train tracks performed marginally more poorly on a visual search task

Table 3. Effects of noise on attention

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Crook & Langdon (1971)	Teachers' reports of concentration.	Aircraft. 75 dBA peak.	(76 teachers) primary and secondary.	Teachers in noisy schools reported more concentration problems in students than did those in quieter schools.
Hambrick-Dixon (1986)	Cross-out letters in quiet or noise.	Train. 108 dBA peak.	(109 black) ages 4-6 yrs.	Children from noisy daycare performed task marginally worse than children from quiet daycare.
Hambrick-Dixon (1988)	Visual stimulus detection with verbal or key press response.	Train. 108 dBA peak.	(102 black) ages 5-7 yrs.	Interaction between location of daycare, response mode, exposure duration, and sex: On key response, girls in noisy daycare less than 2 yrs made more errors than girls in quieter daycare less than 2 yrs. On verbal response, girls in noisy daycare more than 2 yrs made more errors than girls in quiet daycare more than 2 yrs. No differences in performance of boys in any condition.
Heft (1979)	Response latency in visual search.	Noise ratings: 1=low to 7=high.	(94) ages 4-7 yrs.	Higher household-noise level associated with longer response latency.
Karsdorf & Klappach (1968)	Errors and latency on Bourbon test.	Traffic and street. 63-84 phon.	(262) grades 7-10.	Noisy-school students had longer response latency and more errors than quiet-school students.
Ko (1979)	Teachers' reports of concentration.	Aircraft. 105 dBA peak.	(2100 teachers) primary and secondary.	Teachers in noisy schools reported more concentration problems in students than did those in quieter schools.
Kyzar (1977)	Minnesota clerical test.	Traffic and street. 62-94 dBA.	(56) elementary school.	Noise-related deficits in clerical-type task.
Kryter (1985)	Teachers' reports of concentration.	Aircraft. 87 dBA peak.	unavailable.	Teachers in noisy schools reported more concentration problems in students than did those in quieter schools.
Moch-Sibony (1984)	Zazzo sustained attention task.	Aircraft. 29-54 SIL.	(80) kindergarten.	Noisy-school children had poorer sustained attention than did quiet-school children.
Acute noise				
Zentall & Shaw (1980)	Visual search for letters.	Taped class noise from free time (71 dBA) and work time (57 dBA).	(36) grade 2 (hyperactive and non-hyperactive controls).	Noise x Hyperactivity interaction: Hyperactive children made fewer commission errors in low than in high noise conditions; non-hyperactive children unaffected by noise.

Note: SIL = speech interference level.

than did children from relatively quiet daycare centers (Hambrick-Dixon, 1986). In a subsequent study, Hambrick-Dixon (1988) uncovered a more complex relation between chronic noise exposure and attention, utilizing a vigilance task: Gender, exposure duration to train noise at the daycare center, and the response mode for the task (naming versus pressing a key) moderated the association between noise and performance.

Unfortunately, several of the sustained attention and noise studies suffer from methodological shortcomings. The Kyzar (1977) and Karsdorf and Klappach (1968) studies have inadequate controls

for sociodemographic factors. Furthermore, all of the studies are cross-sectional and only the Moch-Sibony (1984) study carefully screened children for normal hearing. The Heft (1979) study relied upon observer ratings of home noise levels, no actual noise measurements were taken.

The Hambrick-Dixon (1988) results are particularly complex and difficult to interpret. One possible explanation for the inconsistency between her results and those of other researchers is that she measured the ability of children to detect a visual signal using tachistoscopic presentation times (100 msec). Thus rather than

Table 4. Effects of noise on auditory discrimination/speech perception

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Cohen et al. (1973)	WAD	Traffic and street. 55-66 dBA.	(54) grades 2-5.	Noise associated with poorer auditory discrimination.
Cohen et al. (1980)	WAD	Aircraft. 95 dBA peak.	(262) grades 3-4.	No effects of noise on auditory discrimination.
Cohen et al. (1986)	WAD	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	No effects of noise on auditory discrimination.
Moch-Sibony (1984)	MP	Aircraft. 29 vs 54 SIL.	(80) kindergarten.	Noise associated with poorer auditory discrimination.
Acute noise				
Blue & Vergason (1975)	GFW	Recorded sounds (unspecified). 55 dBA.	(34) grades 1,3.	Race x Noise interaction: Black children's performance affected more negatively by noise than was white children's performance.
Nober & Nober. (1975)	WAD	Recording of classroom noise vs ambient noise. 39.5-64.7 dBA.	(39) ages 5-7 yrs (healthy control, retarded, and speech-deficit).	Fewer errors when tested in quiet vs. normal classroom noise levels. Control and retarded children performed worse in noise than in quiet; speech-deficit group performed worse in noise than in quiet, but the effect was not significant.
McCroskey & Devens (1977)	WAD	Classroom noise recording. 4 dBA above ambient classroom noise	Unavailable.	Noise associated with decrements in auditory discrimination.
Glenn et al. (1978)	Speech discrimination	Recorded hospital sounds. 75 dB SPC (typical for hospitals).	(21) ages 9-14 yrs (institutionalized MR).	Noise mask significantly degraded speech discrimination.
Laraway (1985)	Digit discrimination	Intermittent white noise. 80 dB SPC.	(46) ages 5-21 yrs (CP, healthy controls).	Noise mask degraded performance of CP children but not controls. Noise effects greatest in younger (< 7 yrs) children.
Laskey & Tobin (1973)	Message comprehension	Speech and white noise. 74 dB SPC.	(22) ages 6-8 yrs (possible LD, non-LD controls).	Speech, but not white noise, interfered with auditory message comprehension in LD children. Control children unaffected by noise.

Note: WAD = Wepman auditory discrimination test, GFW = Goldman-Fristoe-Woodcock auditory discrimination task, MP = Massiot Phillips auditory discrimination test, SIL = speech interference level, LD = learning disabled, CP = cerebral-palsied, MR = mentally retarded.

measuring sustained visual attention, Hambrick-Dixon probably measured signal detectability.

As expected given the physical properties of noise, considerable attention has been given to auditory information processing among children exposed to chronic or acute noise sources. One of the cognitive strategies that children may learn in order to adapt to the distracting properties of chronic noise is to filter or tune out unwanted auditory stimuli. The tendency of children in noisy environments to tune out noise may become overgeneralized, such that various types of acoustic stimuli, including speech, are not attended to carefully (Deutsch, 1964). In a direct

test of the tuning out hypothesis, Cohen et al. (1973) compared the ability of children living in quiet and noisy apartments (proximity to a freeway) within the same building to discriminate between similar sounds under quiet conditions. Cohen et al. (1973) as well as Moch-Sibony (1984) found an association between chronic noise exposure and auditory discrimination (see Table 4). Both of these studies had good controls for socioeconomic status, and pre-screened children for hearing loss. Moreover, Cohen et al. (1973) showed that with longer exposure durations, the association between noise and deficits in auditory discrimination became stronger.

Table 5. Effects of noise on resistance to auditory distractors

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Cohen et al. (1980)	Cross-out letters in ambient or distracting (story recording) condition.	Aircraft. 95 dBA peak.	(262) grades 3-4.	Noise × Month enrolled interaction: with less than 2 yrs enrollment, noisy-school children performed better than quiet-school children under distraction. Between 2-4 yrs enrollment, no noise effects. With more than 4 yrs enrollment, noisy-school children performed worse than quiet-school children.
Cohen et al. (1981)	Cross-out letters in ambient or distracting condition.	Aircraft. 95 dBA peak.	(163) grades 3-4, longitudinal sample.	With 2-4 years enrollment, noisy-school children were less distracted than quiet-school children. With more than 4 yrs enrollment, performance was nearly the same across conditions.
Cohen et al. (1986)	Cross-out letters in ambient or distracting condition.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Children attending noisy schools for 2-4 yrs were less distracted than their quiet-school counterparts. However, after 4 yrs enrollment, performance was nearly the same across conditions.
Cohen et al. (1981)	Cross-out letters in ambient or distracting condition.	Aircraft. 16 dBA reduction in noise-abated classrooms.	(163) grades 3-4, longitudinal sample.	No effects of noise abatement on distractibility.
Hambrick-Dixon (1986)	Weschler IQ task and match animals with color disks in quiet or noise conditions.	Train. 108 dBA peak.	(109 black) ages 4-6 yrs.	Children from noisy daycare performed better in noisy than in quiet conditions. The opposite was found for children from quiet daycare centers.
Heft (1979)	Figure discrimination in matching task in quiet or noise.	Story reading. Noise ratings: 1 = low to 7 = high.	(94) ages 4-7 yrs.	Auditory distraction had less of a negative effect on children from noisy homes than on children from quiet homes.
Acute noise				
Tumure (1970)	Performance and glances away from a visual discrimination task.	Recording of child songs/stories. 60 dBA.	(30) ages 5.5, 6.5, 7.5 yrs.	No noise effects on glances, but performance worse in noisy than in quiet conditions.
Steinkamp (1980)	Multiple perceptual and cognitive tasks.	Classroom sounds and gadgets. Ambient noise.	(24) ages 6-8 yrs (hyperactive, non-hyperactive controls).	Classroom noise and distracting visual materials caused deficits on most tasks. No interaction with hyperactivity.

In two subsequent studies, Cohen et al. (1980; 1986) were unable to replicate these findings on noise and auditory discrimination using a different noise source (aircraft as opposed to traffic). The traffic noise study (Cohen et al., 1973) also drew primarily from working class families; whereas the airport study was conducted in a poverty area. Using a different auditory discrimination task, however, did reveal deficiencies in auditory discrimination in children chronically exposed to noise from airports (Cohen et al., 1986). Children were presented a constant signal (man reading a story) superimposed against four different white noise backgrounds. The task was

to choose the optimum signal to noise ratio. Children who attended noisy schools for longer periods were significantly poorer at this signal to noise discrimination task (see Table 4).

Not surprisingly, the acute noise experimental studies in Table 4 indicate that children have difficulty with auditory discrimination during acute noise exposure (Blue & Vergason, 1975; Glenn et al., 1978; Laraway, 1985; Nober & Nober, 1973). Thus noise can directly interfere with children's ability to discriminate between meaningful auditory stimuli. Noise, particularly irrelevant speech, also interferes with comprehen-

sion of spoken language (Glenn et al., 1978; Laraway, 1985; Lasky & Tobin, 1973). The Glenn et al. (1978) data are noteworthy because the researchers used simulated recordings of an institutional setting for the mentally retarded as their noise 'mask'. Typical, ambient levels from the institution were sufficient to produce marked deficits in discriminating speech sounds among mentally retarded children.

Although there are clear overall trends showing that concurrent noise can mask auditory discrimination, as well as speech, there may be individual differences in these effects. Blue and Vergason (1975) found racial differences in auditory discrimination with black children being more adversely affected than white children by concurrent noise. This study was conducted in the Southeastern United States and may not have controlled for the dialect used in stimulus materials. Laraway (1985) reported that only cerebral palsied children were adversely affected by a noise mask in a task in which children were asked to repeat auditorily presented digits. Lasky and Tobin (1973) revealed that only children with suspected learning disabilities had difficulties in tracking an auditory signal against a background of competing, irrelevant speech. The latter study also showed that speech, but not white noise of a similar volume, interfered with message comprehension.

An interesting and provocative question raised by Deutsch's original hypothesis and some of the subsequent empirical work is whether children chronically exposed to noise become so adept at filtering out noise, that they become resistant to its distracting properties. A number of studies shown in Table 5 present suggestive evidence in support of this hypothesis of differential resistance to noise distractors. However, the data are complex.

Kindergarten children from noisy homes were less distracted by irrelevant speech during a visual discrimination task than those from quiet homes (Heft, 1979). In this task, children selected one of several figures that correctly matched a standard figure. Cohen and colleagues (1980) found a similar pattern of results, but only for elementary students exposed to aircraft noise for two years or less. For those exposed longer, auditory distraction during a visual search task (crossing out e's in a text above reading level of the child) interfered more with the performance of noisy-

school children than it did for quiet-school children. This effect was also replicated in a different sample (Cohen et al., 1986). Hambrick-Dixon (1986) uncovered an even more complex pattern of data on a visual coding task among very young children. In this task preschool children placed colored discs next to animal drawings according to an initial set of model comparisons. For children from noisy daycare centers, performance on this task was better under noisy testing conditions than quiet ones; whereas for children from quiet daycare centers, performance was superior during quiet testing conditions than under noisy ones.

Thus, although there is some evidence that children chronically exposed to noise are less distractable by auditory stimuli during a task, with very long exposure (4+ years), they appear to lose this advantage over non-noise-exposed children. Children exposed for short periods of time to chronic noise, may be able to gate out auditory distractors more effectively during tasks; whereas children exposed for long periods of time, may lose this gating ability. This could occur because despite sustained efforts to gate out unwanted sounds, children learn that this coping strategy is ultimately ineffective since the noise remains as a potent distractor.

The type of task, type of noise, and some individual difference variables also may influence whether concurrent auditory stimuli are distracting during task performance. For example, although both Heft (1979) and Cohen et al. (1980; 1986) found that concurrent speech distracted children during a visual search task (finding target objects in a matrix, crossing out target letters in text, respectively), Hambrick-Dixon (1986) had no main effect of a distractor (background noise of a daycare free play period) on performance of a visual matching task (placement of colored discs next to animal drawings). Turnure (1970) found a distracting effect of speech on school children's performance on a visual discrimination task (choosing the odd geometric shape out of three stimuli). However behavioral manifestation of distraction (glancing up) was not observed. Zentall and Shaw (1980) found that classroom noise recordings did not affect a visual letter search task for normal children and degraded performance for hyperactive, elementary-aged children. Finally, Steinkampf (1980) found that the combination of recorded classroom sounds

Table 6. Effects of noise on memory

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Hambrick-Dixon (1986)	Serial, incidental, visual, paired-associates learning.	Train. 108 dBA peak.	(109 black) ages 4-6 yrs.	No noise effects.
Heft (1979)	Incidental memory of visual stimuli.	Noise ratings: 1 = low to 7 = high.	(94) ages 4-7 yrs.	Higher household noise level associated with poorer incidental memory.
Acute noise				
Fenton et al. (1974)	4 number digit-span.	White noise. 22-72 dBA.	(10 male) ages 9-11 yrs (LD and non-LD).	More errors made in the high noise than in the low noise conditions.
Hygge (1993)	Recall and recognition of reading passage.	Recorded simulations of aircraft, train, traffic, and verbal noise. 66-76 dBA.	(417) ages 12-14 yrs.	Within-subjects analyses revealed a marginal Noise x Source interaction: recall on difficult questions was lower among children in aircraft and traffic noise conditions than in control conditions; no differences in recall in train and verbal noise conditions relative to control condition. Between-subjects analyses also revealed a Noise x Source interaction: recall on difficult questions was lower among children in aircraft noise conditions than in controls; other noise sources did not affect recall. No noise effects on recognition task. Individual differences in learning ability did not moderate noise effects.
Johansson (1983)	Paired-associates learning and letter memory.	White noise. 51 dBA continuous; 55-78 dBA intermittent.	(66) age 10 yrs.	No noise effects.

Note: LD = learning disabled.

played at normal volume and the presence of interesting gadgets were distracting for several tasks among normal and hyperactive boys. Because the latter study did not separate ambient noise from visual distractors, the specific effects of noise cannot be determined.

It is difficult to discern any clear patterns in the above findings on acute, concurrent noise and distraction among children. Speech, as opposed to background noise (e.g., recordings of classroom noise), may be more distracting during task performance. Unfortunately since no studies have used the same task with different aged children, we cannot infer any developmental trends from the data. However it is noteworthy that studies showing no effects tested the youngest children.

Summary

Children chronically exposed to noise may suffer from attentional deficits. Although suggestive,

the work in this area suffers from sufficient methodological flaws (e.g., controls for SES) to prohibit definitive conclusions. Children chronically exposed to noise develop cognitive strategies to cope with the interruptive, distracting influence of noise. Some data suggest that children learn to ignore or tune out auditory stimuli if they have been chronically exposed to noise. At least during the first few years of exposure, children from noisy residential areas appear to be more resistant to acute auditory distractors, presumably because of their enhanced ability to tune out auditory stimuli. These same children may suffer deficits in auditory discrimination. Acute noise distracts children during cognitive task performance, especially when the distractors contain meaningful speech. These acute auditory distraction effects may be more problematic for certain subgroups of children, especially those with some pre-existing cognitive deficits. More research, particularly on groups potentially at risk should be a high priority.

Memory

The noise and memory literature on children (Table 6) is sparse but generally in agreement with the adult literature (Cohen et al., 1986; Smith, in press). There appears to be little or no effects of noise on simple memory tasks from chronic exposure (Hambrick-Dixon, 1986) or acute exposure (Johansson, 1983). However, if sufficient processing demands are placed upon memory, deficits begin to appear in children exposed to noise (Fenton et al., 1974; Hygge, 1993).

Hygge's (1993) experimental findings (see Table 6) are interesting because he compared relatively easy and difficult memory tasks under quiet and noisy conditions, finding that only the difficult tasks were sensitive to noise exposure. Heft's (1979) incidental memory deficits are also noteworthy because they fit with a typical noise and memory finding in adults. The adult incidental memory studies have been interpreted as indicative of attention narrowing or focusing on dominant stimuli (Cohen et al., 1986). Attention narrowing appears to be common under arousing conditions in general (Broadbent, 1971) and under noise specifically (Hockey, 1979). Greater attention to more central cues could lead to poorer encoding of more peripheral material.

Summary

Although there is little research on children's memory under chronic or acute noise conditions, the data are generally in accord with the adult literature on the subject. Noise exposure has little if any effect on children's short term or working memory. Memory tasks that put especially demanding loads on working memory, however, may show some deficits. Narrowing of attention to more central cues under noise may cause poorer memory for incidental information. The potential role of attentional processes in noise-related memory effects warrants further scrutiny.

Intellectual Achievement

Given the reasonable possibility that chronic noise exposure interferes with auditory discrimination and attentional mechanisms, it is not surprising that several researchers have uncovered evidence linking noise exposure with deficits in reading. It is important to note at the onset that unlike chronic effects of noise on cognition, studies of reading and achievement confound chronic and acute noise exposure since they all have relied

upon archival records of achievement tests. As indicated in Table 7, however, the handful of studies of acute noise on intellectual achievement find few if any negative effects. This suggests, indirectly, that the community noise and achievement findings are probably caused by chronic and not acute exposure.

Two clusters of chronic noise associations with intellectual achievement are shown in Table 7. The first group of studies, conducted primarily by Wachs and colleagues, have explored the impacts of early exposure to noise in the home on infants and toddlers. Their work in general finds positive evidence that noise can interfere with normal cognitive development. The findings have been replicated and extended in longitudinal studies (see Wachs & Gruen, 1982, for an overview of this research program). Measurements of cognitive development affected by noise include mental representations of objects, use of objects as tools to achieve goals, and relating words to objects.

One major weakness in Wach's and other research on noise and young children (e.g., Heft, 1979) is reliance on observer ratings of noise exposure rather than actual measurement of physical sound levels. Recently, however Wachs (1988) has validated this measurement approach against decibel meter readings. Another finding that indicates that the effects are due to noise is that access to a secluded quiet room or shelter within the home largely ameliorates the associations between noise ratings and measures of cognitive development (Wachs & Gruen, 1982). Michelson (1968) has found the same buffering effect of a stimulus shelter with home noise levels on elementary school aged children's reading ability. These data on buffering effects of quiet, secluded study spaces in noisy homes raise the possibility, however, that some of the apparent effects of residential noise exposure on cognitive development could be due to residential crowding. It is obviously difficult to disentangle the ecological covariation between these two environmental conditions. Moreover, both of them appear to be associated with deficits in reading acquisition in young children (Evans et al., 1990).

The second group of studies in Table 7, has examined the association between chronic noise exposure at school and/or home with standardized measures of reading and other intellectual achievement tests. With two exceptions, the data

Table 7. Effects of noise on intellectual achievement

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Bronzaft (1981)	Reading.	Train. 6-8 dBA sound reduction in noisy classrooms.	(955) grades 2-6.	After sound reduction with insulation on noisy side of school, students' reading scores on noisy side of school were equivalent to those of students on quiet side of school. In the year before insulation, students on noisy side of school had worse reading scores than students on quiet side of school.
Bronzaft & McCarthy (1975)	Reading.	Train. 59-89 dBA.	(161) grades 2, 4, 6.	Students' reading scores lower on noisy side of school than on quiet side, especially in higher grades.
Cohen et al. (1973)	Reading.	Traffic and street. 55-66 dBA.	(54) grades 2-5.	Noise associated with greater reading deficits in children living in apartments for 4 or more years.
Cohen et al. (1980)	Reading and math.	Aircraft. 95 dBA peak.	(262) grades 3-4.	No noise effects.
Cohen et al. (1981)	Reading and math.	Aircraft. 95 dBA peak.	(163) grade 3-4, longitudinal.	No noise effects.
Cohen et al. (1981)	Reading and math.	Aircraft. 16 dBA sound reduction in noise-abated classrooms.	(163) grade 3-4, cross-sectional.	Noise abatement results in 3rd grade only. Third graders in noise-abated classrooms performed better in math than 3rd graders in non-abated classrooms; 3rd graders in noise-abated classrooms also performed better in reading, but not significantly so.
Cohen et al. (1986)	Reading and math.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	No noise effects.
Gottfried & Gottfried (1984)	BSID, OP, MS, TELD	Noise ratings: 1 = normal level voices in home for 15 min. period to 4 = noise level voices in home for more than half 15 min. period.	(130) 12 mon. infants tested every 6 mon. up to 42 mon.	Higher household noise associated with lower scores on OP at 12-18 mon., on TELD at 39 mon., on BSID at 18 mon., and on MS scores at 42 mon.
Green et al. (1982)	Percent reading below grade level.	Aircraft. 96.2 dBA peak.	(8,240) grades 2-6.	Greater percentage of noisy-school children read below grade level. Effects strongest in higher grades.
Lukas et al. (1981)	Reading and math.	Traffic and street. 70 dBA peak.	(2500) grades 3,6 (100 classes sampled).	Reading scores lower for 3rd and 6th graders in noisier classes. Math scores lower in students in noisier 3rd grade classes, but higher in 6th grade students in noisier classes.
		Ambient classroom and community. 45-75 dBA.		Inverse correlations between community noise and math and reading scores were similar to but less consistent than those between classroom noise and math and reading scores. There also was a synergistic effect of home and school noise on reading.

Table 7. *Continued*

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Wachs et al. (1971)	IPDS	Noise ratings: 1 = normal level voices in home for 15 min. period to 4 = noise level voices in home for more than half 15 min. period.	(102) ages 7, 11, 15, 18, 22 mon.	Higher household noise associated with lower IPDS scores.
Wachs (1978)	SB	Ratings of noise: same as Wachs et al. (1971).	(23) ages 2-3 yrs, longitudinal.	Higher household noise associated with poorer SB performance in boys, no significant effect in girls.
Wachs (1979)	IPDS	Ratings of noise: same as Wachs et al. (1971).	(31) ages 2-3 yrs, longitudinal.	Higher household noise associated with lower IPDS scores in boys and higher IPDS scores in girls.
Wachs & Gandour (1983)	IPDS	Ratings of noise: same as Wachs et al. (1971).	(100) ages 7, 11, 15, 18, 22 mon.	Higher levels of household noise associated with lower IPDS scores, particularly in fussy and irritable infants.
Michelson (1968)	Language, spelling, and math.	Home environment ratings. Scale unavailable.	(710) grades 1-5.	Noise associated with language and spelling difficulties. Noise not associated with math achievement.
Maser et al. (1978)	Reading and math.	Aircraft. 90 dBA peak.	(1917) grades 3, 5, 7, 10.	Noise associated with reading and math deficits in 7th and 10th graders, but only marginal effects on 5th graders. Children with lower aptitudes were most adversely affected by noise.
Acute noise				
Christie & Glickman (1980)	SPM	Recorded classroom noise. 40 and 70 dBA.	(156) grades 1, 3, 5.	Noise × Sex interaction: Boys performed better in noisy than in quiet conditions; girls performed better in quiet than in noisy conditions.
Johansson (1983)	Reading and math.	White noise. 51 dBA continuous, and 55-78 dBA intermittent.	(66) age 10 yrs.	Noise × Intelligence interaction on multiplication and reading performance. Above-average intelligence children solved more multiplication problems in noise than in quiet; below-average intelligence children showed the opposite trend, but noise effects were not significant. Below-average intelligence children tended to have poorer reading speed under noise; there was little difference in reading performance between noise groups with above-average intelligence.
Kassinove (1972)	Math.	Recorded child stories and music. 70-80 dBA.	(80) grades 3,6.	No noise effects on response latency, accuracy, or time-out from task.
Slater (1968)	Reading and math.	Ambient classroom noise, music, stomping and banging, tractor-mower, or quiet crossed with taped white noise. 45-90 dBA and 50-80 dBA white noise.	(263) grade 7.	No noise effects on speed or accuracy.

Table 7. *Continued*

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Weinstein & Weinstein (1979)	Reading.	Classroom: Ambient noise levels during early (noisy) and late (quiet) time of day. 47-60 dBA.	(60) grade 4.	No noise effects.
Zentall & Shaw (1980)	Math.	Taped noise from 2nd grade class. 64 and 69 dBA.	(48) grade 2 (hyperactive, normal controls).	Noise x Hyperactivity interaction: Hyperactive children performed marginally worse in high noise than in low noise; non-hyperactive children performed worse in low noise than in high noise conditions.

Note: BS = Bayley scales of infant development, OP = object permanence scale, MS = McCarthy scales of children's abilities, TELD = test of early language development, IPDS = Piagetian-type measure of infant psychological development, SD = Stanford-Binet test of intelligence, SPM = standard progressive matrix test.

converge on the conclusion of a relation between community noise exposure and reading ability. Several of the studies have good controls for sociodemographic characteristics in the samples and some have screened out children with auditory deficits. Moreover, Green et al. (1982) found a dose response function between noise exposure and reading deficits. Furthermore, the effects in the Bronzaft studies (Bronzaft, 1981; Bronzaft & McCarthy, 1975) cannot be attributed to self-selection. Children were not assigned in any systematic manner to classrooms on the noisy or quiet side of a building located next to elevated train tracks. On the other hand, all of the studies except for Bronzaft (1981) and Cohen et al. (1981) are cross-sectional and neither of these longitudinal studies are prospective. The Bronzaft (1981) findings are particularly important because they indicate that classrooms on the side of an elementary school near elevated train tracks that previously had lower reading scores in comparison to classrooms on the opposite side of the building (Bronzaft & McCarthy, 1975) no longer differed in reading scores following noise insulation in the schools and on the tracks.

The two studies that have not found reliable noise effects on reading may have poor statistical power. Both Cohen et al. (1980; 1986) and Moch-Sibony (1984) tested children from different schools, with different teachers, and in the former case from different school districts. In addition, both restricted their analyses to children from lower grades and did not attempt to tease out the

effects of noise on children of differing ability.

As indicated in several of the citations in Table 7, children in higher grades appear to be more negatively affected by noise exposure on reading than their younger counterparts (cf., Cohen et al., 1973; Green et al., 1982; Lukas et al., 1981; Maser et al., 1978). Children who have lower aptitude or other difficulties may be more vulnerable to the harmful effects of noise on reading (Maser et al., 1978). We also noted earlier several distraction studies indicating more disruptive effects on children with various learning deficiencies. Finally, Lukas and colleagues (1981) uncovered a significant synergistic effect of home and school noise exposure on reading scores.

Summary

Acute noise exposure appears to have little effect on reading and other intellectual activities. During early development, however, residential noise appears to delay cognitive development. In addition, chronic exposure to noise has been associated with reading deficits in seven out of nine studies, particularly for children in higher elementary school grades. There is also evidence that children with lower aptitude and those who also live in noisier homes appear more susceptible to the association of chronic noise exposure at school with reading deficits. The latter trend is interesting to consider in light of attentional data also showing more negative effects of noise exposure on children with pre-existing cognitive deficits.

DISCUSSION

Overview

We know with a good deal of certainty that chronic exposure to noise is associated in children with modest elevations of resting blood pressure, attentional deficiencies, and deficits in reading. Other effects suspected from chronic noise exposure include diminished task motivation, deficits in auditory discrimination, shifts in resistance to auditory distractors, poorer memory when high information processing demands are present, and deficits in infant cognitive development. The latter group of suspected effects include inconsistent data in some cases (auditory discrimination, resistance to distraction) or trends that have only been uncovered in one or two studies (motivation, memory, infant cognitive development). Tables 1-7 provide summary information that forms the bases for these conclusions.

Two major methodological shortcomings are prominent in the literature we have reviewed. Most critically, there is a total lack of prospective, longitudinal designs in this research area. Prospective, longitudinal studies are the strongest, *quasi*-experimental designs that can be applied in field studies and help deal with the host of threats (e.g., self-selection, confounding third variables) that plague correlational designs (see Cohen et al., 1986; Evans & Lepore, in press, for further discussion of methodological problems in field studies of environmental stressors). Such prospective studies must include well matched comparison groups and collect important personal data known to relate to outcomes of interest. Besides their utility as potential control variables in nonexperimental study designs, background variables can enhance statistical power by reducing unexplained variance in the outcome measure of interest. Studies on cardiovascular outcomes, for example, need to collect data on family history of hypertension. Research on reading should collect information on parental education levels and child's intelligence. Prospective, longitudinal designs will have to contend, however, with the potential interfering effects of selective attrition. As documented earlier, Cohen and his colleagues (1981), in one of only two longitudinal studies of noise and children, found that a year later children with the highest levels of blood pressure in their initial

cross-sectional analysis of quiet and noisy schools had moved out of the area. No such selective attrition was found among children in quiet schools.

The second major methodological shortcoming in nonauditory noise research and children has been lack of precision in two aspects of procedural conditions during testing. Testing conditions must be uniform and quiet. Reliance on archival measures of reading, for example, confounds acute with chronic noise exposure since ambient noise sources are likely to be present during the conduct of achievement tests. Testing must occur under quiet conditions in order to determine whether chronic noise affects reading or some other outcome of interest. More thorough audiometric screening is needed in nonauditory studies of noise and children to insure that the effects are not due to hearing loss.

Ecological Perspective

The purpose of this section is to outline some major conceptual shortcomings in the existing work on the nonauditory effects of noise on children and to lay out a preliminary research agenda. An ecological perspective (Bronfenbrenner, 1979) would significantly advance our understanding of this topic. Such a perspective includes greater attention to temporal issues plus the social and environmental contexts in which chronic noise exposure occurs. It also entails examination of the underlying, mediational processes that may link some of the psychophysiological, motivational, and cognitive processes related to chronic noise exposure.

Temporal parameters

Foremost, there has been a severe lack of developmental analyses, except in a few reading studies and in some of Wach's work on infant development in the home environment (see Table 7), of the effects of chronic noise on children. Developmental research approaches are critical in noise studies because it is highly likely that noise has differential impacts on physiological, cognitive and motivational processes as a function of developmental status. Consider for example reading acquisition. It is well established that reading acquisition depends upon the development of certain language competencies (e.g., phonological awareness) that are age

dependent (Mann & Brady, 1988). Noise exposure prior to or following the development of phonological awareness may not affect reading acquisition in the same way as noise exposure during the critical period of phonological awareness learning. Unless a developmental approach is added to noise research, such questions cannot be addressed.

A related but distinct conceptual limitation has been neglect of temporal parameters such as age at time of exposure and history of exposure to noise. For example, several studies on resistance to distractors from noise indicate the effects are contingent upon noise exposure history (see Table 5). Children exposed to ambient noise levels for shorter periods of time appear to be more resistant to the distracting properties of noise (see Table 5). The findings could relate to work on motivational deficiencies from prolonged noise exposure. Perhaps children attempt to filter out noise during early periods of exposure but eventually give up on this strategy. Duration effects could also relate to the specificity of resistance to auditory distractors. It would be interesting, for example, to investigate children's ability to filter out aircraft noise versus white noise or irrelevant speech, as a function of length and type of chronic noise exposure.

Unfortunately, we cannot disentangle age effects from exposure duration effects. For example, the apparently stronger linkages between chronic noise exposure and reading scores among older children (see Table 7) could be a function of a critical period of exposure or the result of longer, cumulative adverse impacts. Related to this latter option, we know nothing at this stage about the long-term effects of early childhood exposure to noise. What happens in later childhood or adolescence to children who spend all or part of their early years attending school or living near an airport or busy street?

Context

Greater attention to the ecological context in which chronic noise exposure occurs may prove fruitful for future research on noise and children. This ecological context might include more ecologically valid noise exposure estimates, attention to the indirect effects of noise on children via adult caregivers, and measurement of other social and environmental conditions covarying with chronic noise exposure. With one

exception (Lukas et al., 1981) none of the field studies of noise and children have attempted to calculate overall noise exposure. It may be recalled that Lukas and colleagues found a synergistic effect of home and school noise exposure on reading.

Furthermore, the noise estimates that researchers have relied upon do not take into account children's mobility, exposure to noise sources in the home, or the attenuation properties of the structures they inhabit.

Nearly all of the work on noise and children involves comparisons between noisy and quiet settings. With one exception, Green et al. (1982), there is no information on dose response functions. Besides its evidentiary value, dose response curves would have public policy importance. We currently are unable to provide clear statements about what level of noise is harmful for children or to say what the efficacy would be of providing specific sound attenuation interventions.

Not only are children attending school or residing in homes in noisy areas exposed to noise but so are their principal caregivers. The behaviors of caregivers in noisy settings could indirectly influence children's responses to noise (Bronfenbrenner, 1979). For example, perhaps parents in noisy homes do not speak to their children or read to them as often as parents in quieter neighborhoods. Classroom observations and teachers' self-reports indicate that aircraft or train noises interrupt teacher lecturing (Crook & Langdon, 1974; Kyzar, 1977; Moch-Sibony, 1974), in one study causing a 10% reduction in total teaching time (Bronzaft & McCarthy, 1975). It is also well documented that teachers in noise-exposed classrooms report greater annoyance and fatigue during the school day in comparison to teachers from quiet classrooms (Crook & Langdon, 1974; Ko, 1979; 1981; Sargent et al., 1980). Therefore some of the adverse effects of noise on child development could be mediated through the negative impacts of noise on the child's primary caregivers. Parents and teachers may have less patience and energy to devote to children because of the adverse effects of noise on themselves. More directly, noise may alter the manner in which parents and teachers instruct children, altering reading or speaking patterns. Recent data indicate that parent-child interactions may be affected by household noise levels. Parents from noisier homes appeared less

interested in their children's activities and talked less with their children (Wachs, 1989; Wachs & Camli, 1991). Controls for education levels of the mother did not change these findings.

Ambient noise exposure rarely occurs in isolation of other social and environmental problems. Noisy environments frequently covary with crowding and pollution and are often part of the fabric of poverty, including substandard housing, conflictual households and various other psychosocial strains. Although the ecological covariation of noise with other adverse environmental and social factors makes it difficult to isolate the effects of noise on children, we should be mindful that the harmful effects of noise may be amplified by the context in which noise is often embedded. It may be precisely those children who develop under such impoverished physical and social circumstances who are most vulnerable to the harmful effects of noise (Bronfenbrenner, 1979; Evans et al., 1990). We have recently found among adults, for example, that the negative effects of residential crowding on psychological distress are significantly worsened by chronic strains associated with poverty (e.g., insufficient utilities, poor housing quality, financial insecurities) (Lepore et al., 1991).

Noise levels may also operate within a context of important individual differences among children. There is some evidence that some children are more at risk for adverse noise effects on cognitive development. Less intelligent children's math and reading performance appears more sensitive to noise exposure (Johansson, 1983; Maser et al., 1978). Studies of young children and infants suggest greater susceptibility to chronic noise-related problems among boys in comparison to girls (Wachs, 1978; 1987; 1989). On the other hand, girls may be more distracted by acute noise exposure (Christie & Glickman, 1980; Hambrick-Dixon, 1988). Cognitive performance during acute noise appears to be disrupted more by noise for individuals with pre-existing learning deficits (cerebral palsy, learning disabled).

In addition to alerting researchers and policy makers to the potential of subgroups of children at high risk for negative effects of noise, these findings also have another important implication. Some of the small or even conflicting nonauditory effects of noise reviewed herein may be conservative estimates of noise effects since they by and large have not examined interactive effects.

While in some cases there may be little if any overall noise effects on children, it would be erroneous to conclude from such data profiles that noise is an inconsequential environmental problem for children. There may be large segments of the child population whose development may be significantly compromised by noise exposure early in life.

Mediational processes

Another area of future research that might emanate from an ecological perspective on noise and children is greater scrutiny of the potential interplay among the various psychophysiological, cognitive, and motivational processes that appear to be affected by chronic noise exposure. Cohen and his colleagues (1973) examined Deutsch's (1964) hypothesis that children chronically exposed to noise may learn to tune out auditory stimuli indiscriminantly and thus not pay sufficient attention to speech. They found that children from noisier apartments were deficient in auditory discrimination. Of particular interest, this deficiency significantly accounted for the poorer reading abilities of the noise-exposed children. This study stands alone as the only analysis of an underlying process to explain how noise affects children.

Given the findings (see Table 4) that noise can mask speech and evidence that speech perception and other linguistic skills such as phoneme awareness are critical precursors to reading acquisition (Mann & Brady, 1988), more work is called for on the effects of chronic noise exposure on psycholinguistic processes and their potential mediating link with reading. Other pathways warranting further investigation include those between chronic noise exposure, motivation, attention, and reading.

There are also plausible interconnections among chronic noise exposure and several of the cognitive processes we have reviewed. For example, people chronically exposed to noise may become more resistant to the distracting effects of acute noise exposure during a task because they can ignore or filter out auditory distractors. This ability may occur as a result of learning to tune out or filter auditory sounds. Thus one would expect a relation between the ability to ignore auditory distractors and deficits in auditory discrimination associated with chronic noise exposure. Analogously, we would expect a mediational pathway

between chronic noise exposure, attentional focusing and deficits in incidental memory performance.

Thus rather than only treating different outcome variables such as reading, attentional processes, and resistance to distraction as separate correlates or effects of noise exposure, more thought and careful analyses are required to investigate how these variables may form causal links to one another. In other words, both the direct and indirect pathways of the nonauditory effects of noise on children need to be investigated. From a theoretical and public policy perspective, this is perhaps most crucial in the case of reading. Although stronger data on the adverse effects of chronic noise exposure on reading would be valuable from an evidentiary point of view, what is of paramount importance now is a shift in focus to explanations of why and how chronic noise adversely influences reading acquisition.

There may also be some potent interplay among psychophysiological processes and some of the cognitive strategies apparently influenced by chronic noise exposure. For example, presumably it takes some effort to tune out or ignore noise. Experimental data as well as field studies with adults indicate that cognitive efforts to maintain task performance during noise come at a price of heightened sympathetic arousal (Tafalla & Evans, 1993; Welch, 1979). When performance suffers under noise, slight or no sympathetic arousal is apparent. However, if performance is maintained under noise which is possible except under tasks of very high load demands on attention and working memory (Cohen et al., 1986; Smith, in press), then indices of sympathetic arousal should be substantially elevated during noise exposure.

The associations between chronic noise exposure in children (see Table 1) and heightened blood pressure raise several important questions about mechanisms. For example, are blood pressure elevations caused by repeated sympathetic arousal induced by the distracting and interfering properties of community noise conditions? Alternatively, are the elevations mediated by adrenocortical activity and thus primarily indicative of chronic stress? To our knowledge, no analyses of various psychoneuroendocrine pathways between noise and blood pressure elevations have been investigated. Given the central role of cognitive appraisal in psychological

stress, it would also behoove researchers to examine whether psychosocial factors such as perceived control, self-confidence to ignore/tune out noise, or annoyance, moderate the effects of noise on blood pressure and other psychophysiological processes among children.

Another fruitful area of psychophysiological research would be to investigate the potential role of chronic noise exposure in cardiovascular reactivity. Individual differences in reactivity to standard psychosocial elicitors of stress (e.g., mental arithmetic) may be predictive of cardiovascular disease (Krantz & Manuck, 1984; Matthews et al., 1986). Research on cardiovascular reactivity in both adults and children has ignored the potential etiological role of chronic exposure to environmental stressors. More detailed analyses, focusing on possible behavioral toxicological effects of in utero or neonatal noise impacts are also called for. This is especially pertinent in light of contemporary medical practices such as ultra sound monitoring or placement of premature infants in neonatal intensive care units.

Large numbers of children both in America and, in rapidly growing numbers in the Third World, are being exposed to levels of ambient noise that are not only a threat to hearing but may have harmful effects on physiological and cognitive development. The potential for harmful effects from chronic noise exposure on children's development is great; what we know with certainty about the problem is, unfortunately at the moment, insufficient. At the same time, there is a foundation of evidence clearly suggesting potentially harmful effects from chronic noise exposure among children. We also have enough data on hand to formulate preliminary models of underlying, mediating mechanisms that could account for the effects of noise. It is also clear that more longitudinal work with prospective designs is crucial to definitively demonstrate the relationships between chronic noise exposure and children's development. Such designs afford stronger internal validity given the impossibility of randomly assigning children to varying community noise levels. Longitudinal designs allow us to examine changes in behaviors over time plus provide the opportunity to examine whether self-selection has occurred prior to noise exposure.

ENDNOTE

This article is based in part on earlier presentations at the Fifth International Congress on Noise as a Public Health Problem, Stockholm, Sweden and A Strategy for Noise Prevention in the 90's, American Speech and Hearing Association, Washington, DC. Preparation of this article was partially supported by the National Heart Lung and Blood Institute, RO1 HL47325-01A1, the Nordic Noise Council, and the Swedish Environmental Protection Board.

ABSTRACT. The percent of students reading below grade level from 1972 to 1976 was regressed on racial, socioeconomic, educational, and noise level variables for all elementary schools in Brooklyn and Queens, New York. Schools were assigned noise exposure scores based on Noise Exposure Forecast contours for New York City airports. The correlations between these noise scores and a variety of noise level metrics ranged from 0.74 to 0.97. The regression coefficients adjusted for confounding factors, indicated that an additional 3.6% of the students in the noisiest schools read at least 1 yr below grade level with 95% confidence limits from 1.5 to 5.8%. The dose-response relationship indicated that the percent reading below grade level increased as noise level increased.

SEVERAL STUDIES have examined the effect of exposure to high levels of environmental noise on children's reading ability. Cohen et al.¹ found that elementary school students living for at least 4 yr on the lower floors of an apartment complex above a heavily trafficked bridge in New York City showed greater impairment of reading ability than those living on higher floors. Indoor noise levels varied from 66 decibels (dB) on the lower floors to 55 dB on the higher floors. When differences in parental education level were controlled, however, the correlation between floor level and reading test scores was reduced to marginal statistical significance in the 54 students tested. No effect was observed in children living in the complex

for less than 4 yr, suggesting that the effect resulted from chronic noise exposure.

Bronzaft and McCarthy² found a statistically significant decrease in mean reading test scores of elementary school students whose classrooms faced an elevated subway line compared to pupils in the same school whose classrooms faced quiet streets. Noise levels increased to 89 dB whenever an elevated subway train passed by, but on the quiet side the noise level remained at 59 dB. Classrooms did not differ in overall intellectual or achievement level and pupil assignment to classrooms was random. However, the possibility that the observed differences in reading test scores were due to noise distraction while the students were taking the test was not eliminated.

Maser et al.³ reported that children who attended school under the Seattle-Tacoma airport flight paths showed a deficit on standardized tests of scholastic achievement compared to students in quiet schools. The deficit increased as the students continued in the noisy schools, becoming statistically significant by the seventh grade. The deficit was evident within groups of students divided into thirds based on their initial academic aptitude. However, other differences between the schools, such as teacher training or ability, racial composition, and socioeconomic level of the student body were not controlled.

Cohen et al.⁴ reported that reading and math test scores of third grade students in noise-abated classrooms were higher than those in classrooms without noise abatement after adjusting for race, number of months in school, and mean cognitive ability of the class measured in the first grade. Only the differences in the math test scores were

statistically significant. Students in the noise-abated classrooms, however, also scored higher than students in quiet classrooms in schools far away from the Los Angeles International Airport, the source of noise in this study. These quiet schools were in a different school district, and the authors believed that the different administration policies, quality of teaching, and level of Federal aid were more important than noise exposure in affecting performance on reading and math tests.

In summary, these studies suggest that elementary school students who live and attend school in noisy environments have reduced scores on reading tests. However, these studies have examined only a few selected schools and they have not examined the effects of different levels of noise exposure on reading ability. This study was designed to answer these objections. This study utilizes the vast amount of data on every school collected by the New York City Board of Education for several years and the published noise exposure contour maps for the major New York City airports. Multiple linear regression was used to control for confounding factors and to assess the significance of the noise exposure.

METHODS

Noise exposure estimation. Brooklyn and Queens elementary schools were divided into five groups based on Noise Exposure Forecast (NEF) contours for John F. Kennedy (JFK) and LaGuardia airports. Schools in each noise group were assigned a noise exposure score of 0, 1, 2, 4, or 8. Because of the large reduction in the size of the noise-impacted areas around JFK during the period under study, 1972-76, two sets of noise exposure scores were used. The first set, called the Noise 70 scale was based on 1970 contours for JFK⁵ and 1972 contours for LaGuardia.⁶ The second set, the Noise 78 scale, was based on 1978 contours for JFK⁷ and the same 1972 contours for LaGuardia. The criteria used to group the schools, the number of schools, and the noise exposure scores assigned to each group using the two noise scales are presented in Table 1.

Since the noise levels were not measured in the 362 schools, summary values from the long-term 24-hr noise measurements made by the Federal Aviation Administration⁸ and by Tom O'Hare of the Environmental Protection Agency (personal communication, 1978) were compared with the noise scores assigned to the measurement locations to examine the validity of the noise scales. Since the noise

scales were designed to measure only the relative noise exposure levels of the different schools, the product moment correlation between the noise scores and the noise levels is an appropriate measure of agreement. The results, presented in Table 2, indicate good agreement between the noise scales and a variety of noise level metrics. The correlations with the Noise 78 scale ranged from 0.81 to 0.97 and the correlations with the Noise 70 scale were lower, 0.74 to 0.91, as would be expected since the noise measurements were taken between 1975 and 1978. Thus, the grouping of schools by the NEF contours and the assignment of noise scale values seem to have enough validity to justify their use in a preliminary study where the expense of obtaining more exact estimates of the noise level in each of the 362 schools would be prohibitive.

Reading test statistics and other data. A magnetic tape obtained from the New York City Board of Education contained the aggregate results of the annual nationally standardized tests of reading ability given in the New York City public schools and data on racial composition, socioeconomic level, and various educational factors for each school during the period 1972 to 1976. The dependent variables used in this study were the percent of students in each grade whose test scores placed them either 1 or more yr below grade level, or 2 or more yr below grade level. The independent variables taken from the tape include the percent of students in each of five ethnic groups, the percent eligible for free lunch programs, the absentee, admissions and departure rates, the pupil-teacher ratio, the percent of teachers with 5 or more yr experience, and the percent of teachers on two pay scales which reflect the amount of post-baccalaureate education. The data for these variables were based on the entire school with the exception of the racial composition data which were specific for each grade after 1973. The means and standard deviations of the variables used in the regressions are presented in Table 3. As an example of the distribution of the dependent variables, Figure 1 presents a histogram of the percent of fourth grade students reading 1 or more yr below grade level.

The percent of students reading below grade level in each grade was regressed on the independent variables for each of the years 1972 to 1976 and for all 5 yr combined. The data from each school were weighted proportionally to the number of students who took the reading test. Regressions using the combined 5-yr data included indicator variables for the different years to allow for temporal

changes in the mean reading level. Squared, square root, and interaction terms for the percent Black, percent Puerto Rican, and the percent eligible for free lunch programs were included in the regressions to remove abnormal trends in the plots of residual values against these variables.

The relationship between the level of aircraft noise exposure and the percent reading below grade level, the dose-response relationship, was examined by regression analysis using indicator variables for each of the noise level groups instead of a single variable with the noise scale val-

ues. This method of analysis is explained further in the Appendix.

RESULTS

Noise scale variable coefficients. The partial regression coefficients for the noise scale variables (b), their two-tailed level of statistical significance (P value) and the square of the multiple correlation coefficient (R^2) are presented in Table 4 for the regressions using the combined 5-yr data. All of the coefficients are positive, indicating that

Grade	b^* (Noise 78)	P Value†	$R^2‡$	b (Noise 70)	P Value	R^2

5	0.375	.038	0.62	0.481	.001	0.62
6	0.541	.016	0.67	0.259	NS	0.67

* b = Partial regression coefficient.
† P Value = two-tailed level of statistical significance.
‡ R^2 = Square of the multiple correlation coefficient.
§NS = Not statistically significant.

the percent reading below grade level was higher in the noise-exposed schools. The coefficients were statistically significant at the .05 probability level in 15 of 18 regressions.

The coefficients from the regressions of the percent reading 1 or more yr below grade level range in magnitude from 0.263 to 0.926. By weighting each of these coefficients proportionally to the average number of students in that grade and inversely proportional to the variance of the coefficient, a summary coefficient of 0.62 with 95% confidence limits of 0.51 to 0.74 can be obtained.⁹ Since regression coefficients estimate the average change in the dependent variable that accompanies a one unit change in the independent variable, this coefficient suggests that a one unit increase in noise score would be accompanied by an increase of 0.62% in the number of students reading 1 or more yr below grade level in an average school.

The coefficients from the regressions using yearly data, which are not shown, were occasionally negative (11 of 90). Forty-one coefficients, all positive, were statistically significant. For the last 3 yr of the study, for which grade-specific racial composition data were available, all the coefficients were positive and 37 of 54 were statistically significant. These coefficients were of similar magnitude within each combination of grade, reading test statistic, and noise scale, indicating stability in the estimates of the effect of noise using data from different years.

Dose-response relationship. The difference in the percent reading 1 or more yr below grade level in the various noise exposure groups, as extrapolated from the indicator variable coefficients, is presented in Figure 2 along with a dotted line representing the linear dose-response relationship assumed by the use of the noise scale. The increase

in the indicator variable coefficients with increasing noise score was statistically significant indicating that the percent reading below grade level increased with increasing noise level. Although the percent reading below grade level appears to be higher than the linear dose-response relationship at moderate noise levels, and less than the linear relationship at high levels, tests of the goodness of fit, described in the Appendix, indicated that there was no significant improvement when the indicator variables were used rather than the noise scale variable in three of four

Fig. 2. Dose-response relationship between aircraft noise scale values and the difference in the percent reading below grade level in the noise scale zero group of schools and each of the other groups. Point estimates and 95% confidence limits for the effect at each level are plotted along with a dotted line representing the linear dose-response relationship assumed by the use of the noise scale values.

regressions. Thus, the data are largely compatible with a linear dose-response relationship.

The actual level of reading impairment in the different noise exposure groups can be directly estimated from the dose-response curve. The mean difference in the percent reading 1 or more yr below grade level in the noisiest schools, those within the NEF 40 contour, compared to the quietest schools, outside the NEF 30 contour, is 3.6% with 95% confidence limits from 1.5% to 5.8%.

DISCUSSION

Several limitations of this study need to be considered: (1) the noise exposure scale, (2) pupil transfers, (3) the variables used to control confounding, and (4) the aggregate nature of the statistics.

Although we do not know whether the effect of noise on reading ability is best related to the noise energy level, peak noise level, the amount of time the noise is above a certain level or some other metric, the noise scale used in this study correlated well with a variety of noise metrics. Thus it is doubtful that the use of another metric with the noise contours generated from it would result in a substantially different division of schools into noise groups. The results would, therefore, be similar if another noise scale were used.

The average noise exposure of all the students in a school zone is derived from local and domestic noise sources as well as aircraft. Examination of neighborhood noise contours¹⁰ indicated that the effects of local noise sources, such as elevated subway trains and heavily trafficked streets, were greatly reduced only a few blocks from the source. Thus it is doubtful that these noise sources would substantially alter the average noise exposure for all the students. Domestic noise exposure could not be directly estimated, therefore the results of this study depend on the assumption that this factor does not substantially confound the analysis.

Although elementary schools draw the vast majority of their pupils from the immediate neighborhood, transfers are allowed for a variety of reasons. If poor readers tended to transfer from noise-exposed schools into nonexposed, the noise variable coefficients would be decreased. Analysis of such transfers indicated that more poor readers transferred into nonexposed schools than would be expected from the percent of all students in nonexposed schools.¹¹ However, the number of such transfers, about 2% of the school population was too small to greatly affect the regression coefficients. Transfers of minorities for purposes of racial balance have also generally been from noise-exposed to nonexposed areas. These transfers would also tend to decrease the magnitude of the noise variable coefficients because these students, who are likely to be poor readers, are counted in the nonexposed schools although they live in noise-exposed areas. Thus, due to transfers, the noise variable coefficients would tend to underestimate the effects of noise on reading ability; however, the bias would probably be small.

Although this study includes adequate measures of many factors which affect reading ability, the only variable which directly measures the important factor of socioeconomic status is the percent of students eligible for free

lunch programs, the number of low income families. The racial composition variables are also highly correlated with socioeconomic status, and the use of squared, square root and interaction terms allows the model to accommodate nonlinear effects of these variables. Although it is doubtful that additional measures of socioeconomic level, such as parental occupation or educational level, would alter the results, they would be useful to demonstrate the adequacy of control over this important factor.

It is possible that there are other factors strongly correlated with both noise levels and reading ability and which would, therefore, affect the noise variable coefficients. However, an examination of maps constructed from basic racial, socioeconomic, educational, and residential data from the 1970 census¹² failed to reveal any factors which were strongly correlated with the noise contours around both airports. Census data were not included in the regressions because there are often considerable differences between the general population in a census tract and the families from that tract that have children in the public schools.

The major limitation of this study is the aggregate nature of the statistics which preclude examination of individual reading ability. Factors which affect the percent reading below grade level may not have the same effect on individual reading ability. To measure the effect of noise on individual reading ability, it would be necessary to relate each student's noise exposure from all sources to the student's reading test scores controlling for race, socioeconomic level, and other confounders. Such a study is recommended.

CONCLUSIONS

Although the conclusions of this study must be qualified because of the less-than-ideal measures of noise exposure and socioeconomic level that were available and the aggregate nature of the statistics, the results support the hypothesis that high levels of environmental noise are inversely related to reading ability in elementary school children. The regression coefficients indicate that an additional 3.6% of the students in the noisiest schools read at least 1 yr below grade level with 95% confidence limits from 1.5% to 5.8%. The dose-response relationship suggests that the percent reading below grade level increases with increasing noise level.

The Environmental Protection Agency estimates that 15% of the U.S. population is exposed to average noise levels above 65 dB and 1.5% is exposed to levels above 75 dB¹³ which are roughly equivalent to the noise levels at the NEF 30 and 40 contours, respectively. Since this study and others suggest that some children exposed to these noise levels would have decreased reading ability, additional studies are necessary to determine more precisely the extent of the reading impairment at environmental noise levels.

APPENDIX

The use of indicator variables to estimate the dose-response relationship is similar to using analysis of covari-

ance to estimate the effects of different levels of a non-metric factor (the noise exposure groupings) while adjusting for all the other variables listed in Table 5. Four indicator variables were used to code for each group of schools, using the schools assigned a noise score of zero as the reference group. All four indicator variables were given a value of zero for these schools in the reference group. Each of the other groups of schools had an indicator variable which was assigned a value of one for that group and zero for the other three. Thus the first indicator variable was coded zero for all schools except those assigned a noise scale value of one.

The coefficient for each indicator variable from the multiple regression analysis estimates the mean difference in the percent reading below grade level between the schools coded for by that indicator variable and the reference group, adjusted for the effects of the other variables. For example, the coefficient for the first indicator variable from a regression of the percent of fourth graders reading 2 or more yr below grade level was 0.867 (not given elsewhere in this paper). Thus, 0.867 was the average difference in the percent reading below grade level between schools with a noise score of one and those with a noise score of zero on the Noise 78 scale.

To combine this estimate of the effect of noise in that group of schools with estimates from other regressions, it was necessary to take into account the differences in the coefficients that result from using different grades and reading test statistics. These differences were eliminated by dividing the indicator variable coefficients by the noise scale variable coefficient obtained from regression on the same data. This standardized ratio expressed the change in reading ability in multiples of the noise scale variable coefficient. In this example, the noise scale variable coefficient was 0.688, as given in Table 4, and the ratio was 0.867/0.688, or 1.26.

The standardized ratios and the weighted averages for each noise scale group are presented in Table 6. Since these ratios are not as readily understood as the percent reading below grade level, the averages were transformed back into the latter by multiplying each by the summary noise scale variable coefficient, 0.62, for Figure 2. Thus, in the highest noise scale group, the weighted average of the noise scale variable coefficient was 5.9 which when multiplied by the summary noise scale variable coefficient, yields the estimate that an additional 3.6% of the students in an average-sized school in the noisiest zone would read at least 1 yr below grade level compared to schools in the quietest area.

In addition, the degree to which the regression model with the indicator variables fits the data better than the model with the noise scale variable can be determined from the difference in the sum of squares due to regression for each model. This difference divided by the number of additional parameters used, 3, and by the mean square due to error can be tested against the *F* distribution to determine the probability that chance alone could account for the difference in the sum of squares. The results, presented in Table 7, indicate that chance could easily account for the differences in the goodness of fit in all but one case.

Further details on the use of indicator variables in regression analysis can be obtained from several textbooks.^{14, 15}

Abstract—Before the opening of the new Munich International Airport and the termination of the old airport, children near both sites were recruited into aircraft-noise groups (aircraft noise at present or pending) and control groups with no aircraft noise (closely matched for socioeconomic status). A total of 326 children (mean age = 10.4 years) took part in three data-collection waves, one before and two after the switch-over of the airports. After the switch, long-term memory and reading were impaired in the noise group at the new airport, and improved in the formerly noise-exposed group at the old airport. Short-term memory also improved in the latter group after the old airport was closed. At the new airport, speech perception was impaired in the newly noise-exposed group. Mediation analyses suggest that poorer reading was not mediated by speech perception, and that impaired recall was in part mediated by reading.

A consequence of modern means of transportation is widespread noise exposure. In Europe, almost 25% of the population is exposed to equivalent noise levels (L_{eq}) of 65 dBA or more (Berglund & Lindvall, 1995). At this level, annoyance is marked, sleep is disturbed, and some cognitive processes are impaired (Cohen, Evans, Stokols, & Krantz, 1986; Evans & Lepore, 1993; Smith & Jones, 1992). Noise exposure is consistently correlated with reading deficits and may interfere with speech perception and long-term memory in primary-school children (Evans & Lepore, 1993).

The simultaneous opening and closing of the new and former Munich Airport provided us with an unprecedented opportunity to conduct a prospective study of the effects of aircraft noise on children. This is the only prospective study of nonauditory effects of noise on children that has been undertaken. Moreover, cessation of noise at the old airport provided a unique opportunity to assess whether expected, noise-related impairments are reversible. Sociodemographically matched control groups exposed to little aircraft noise were formed at both airports. By testing the children in silence and not in everyday-noise settings, we eliminated confounds between chronic versus acute noise. Furthermore, examination of the interplay among attention, memory, and reading over time enabled us to test whether expected noise-related reading deficits could be accounted for by shifts in underlying cognitive processes.

Previous cross-sectional research (Cohen et al., 1986; Cohen, Glass, & Singer, 1973; Evans & Maxwell, 1997) indicated that noise-related reading deficits might be mediated by a cognitive strategy wherein children become less attentive to auditory stimuli as a way to cope with noise. It is unclear whether such shifts in attentional strategies are general to noise

or specific to speech. Laboratory noise also impairs both long-term memory (Hygge, 1997; Hygge, Boman, & Enmarker, in press) and short-term memory (Hamilton, Hockey, & Rejman, 1977; Hockey, 1979). Both speech perception and memory are related to reading acquisition (Crowder & Wagner, 1992; Mann & Brady, 1988).

In summary, we collected prospective data to assess how children's reading was affected by changes in ambient noise levels caused by modified airport operations. In addition, we investigated two cognitive processes, attention and memory, implicated in prior experimental work on acute noise exposure, and how they relate to speech perception.

METHOD

Design and Subjects

The two experimental groups comprised children who were (old airport) or would be (new airport) exposed to aircraft noise. The two control groups were selected from areas that had little exposure to aircraft noise. The control groups were matched with their respective experimental groups on the basis of sociodemographic characteristics. One wave of data collection started 6 months prior to the changeover of airports, the second wave was 1 year later, and the third wave 2 years later. A total of 326 children participated: 43 in the old-airport, no-noise group; 65 in the old-airport, noise group; 107 in the new-airport, no-noise group; and 111 in the new-airport, noise group. Their ages ranged from 8 to 12 ($M = 10.4$, $SD = 0.85$). The children at the new airport were tested 3 to 5 months before the children at the old airport, but there was no difference in average year of birth. Criteria for taking part in the study were a minimum of 2 years of residence and German fluency, which ruled out confounds with ethnicity. Normal hearing, as assessed by audiometric screening, was also a criterion for participation. The experimental and control groups at the two airports did not differ in age, gender, ethnicity, number of family members, parental occupation, or education, and attrition did not differ among the four groups, $\chi^2(3, N = 326) = 1.64, p > .10$.

Procedure and Materials

At each data-collection wave, the children were tested individually in silence for 1.5 hr on 2 consecutive days in a specially designed temperature-controlled and sound-attenuated mobile laboratory that traveled to their schools. The children worked individually on an array of different tasks. In this article, we present only the cognitive dependent measures. (For data on physiological stress and mental health, see Bullinger, Hygge, Evans, Meis, & von Mackensen, 1999; Evans, Bullinger, & Hygge, 1998; Evans, Hygge, & Bullinger, 1995.)

Aircraft Noise and Children

Reading

A standardized German reading test was employed (Biglmaier, 1969). The children read paragraphs and word lists of increasing difficulty. Some of the words in the lists were pseudowords, but phonologically appropriate in German.

Memory

On the first day, the children read a text in intermittent broadband noise at 80 dBA L_{eq} , and the number of lines read within the 12-min time limit was noted. On the second day, the children were tested for long-term memory (recall) in silence. We introduced noise exposure during encoding to make the task more difficult. Children's performance on this test is sensitive to acute noise exposure (Hygge, 1997). For the short-term memory test, strings of consonants were presented one per second over headphones. Randomly, the sequence was stopped, and the children were asked to write down as many consonants as they could remember, in the correct position, starting at the end of the sequence. Letters in the correct or adjacent positions were scored as correct. Acute noise is known to impair performance on this task (Hamilton et al., 1977).

Attention

Two indices of general attention were used: visual search and reaction time. The visual search task is sensitive to ventilation noise (Hygge, 1991) and chronic stress (Baum, Gatchel, & Schaeffer, 1983). For this task, the children were presented with 12 complex figures and 5 simple target figures and asked to identify which one of the target figures was embedded in each complex figure. In the reaction time task, the children responded to random occurrences of red and green lights by pressing two different buttons. The children performed this task first in a silent 5-min session and then in an equally long session with aircraft noise at 85 dBA L_{eq} .

Speech perception

The speech perception measure was adapted from Hygge, Rönnerberg, Larsby, and Arlinger (1992). The children heard a story against different noise backgrounds (aircraft noise, road noise, and broadband noise) and used buttons labeled "+" and "-" to adjust the sound level of the story when it dropped randomly by 10 dBA. They were instructed to readjust the volume to the point where they could understand what was said if they concentrated. Noise-exposed children appear to ignore or tune out speech-relevant stimuli (Cohen et al., 1973, 1986; Evans & Maxwell, 1997) and are expected to require better signal-to-noise ratios than children who have not been exposed to noise.

RESULTS

Noise Levels

Noise levels were measured with a Brüel & Kjær (Copenhagen, Denmark) Community noise-level analyzer for a 24-hr period during data collection at the mobile laboratory. The expected changes in noise levels were observed at both airports (see Table 1).

Table 1. Noise levels (24-hr dBA L_{eq}) before and after the airport switch

Airport and group	Before switch (Wave 1)	After switch (Wave 3)
Old airport—aircraft noise	68	54*
Old airport—no aircraft noise	59	55
New airport—aircraft noise	53	62
New airport—no aircraft noise	53	55

*This number is an average from Waves 2 and 3 because there was only one observation in Wave 3, at a suspect value of 49.

Reading

On the word-list part of the reading test, only difficult words showed differences between the groups (see Fig. 1). The Airport \times Group \times Wave interaction was significant, $F(2, 252) = 5.10$, $p = .007$. (All F tests with repeated measures of wave were treated as multivariate analyses of variance, MANOVAs, rather than univariate analyses of variance, ANOVAs. These MANOVAs yield higher p values,

Fig. 1. Mean number of errors on the difficult word list as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

and thus are more conservative, than the corresponding univariate epsilon-corrected Greenhouse-Geisser ANOVAs.) Separate *t* tests (two-tailed throughout, except as noted) showed a difference between groups at the old airport at Wave 1, $t(99) = 2.68, p = .009$, but not at Waves 2 and 3 ($ts < 1$). At the new airport, there was a marginal difference between groups at Wave 3, $t(154) = 1.80, p = .074$, but not at Waves 1 and 2 ($ts < 1$).

The results for the prose component of the reading test were similar to those for the word-list test, but not as marked. For the most difficult paragraphs (Numbers 8–12), there was a weak Airport \times Group \times Wave interaction, $F(2, 172) = 2.16, p = .118$ (see Fig. 2). Separate *t* tests revealed a difference between groups at the old airport at Wave 1, $t(82) = 2.79, p = .007$, but not at Waves 2 and 3 ($ts < 1$). At the new airport there were no significant effects.

Memory

On the long-term recall task (see Fig. 3), there was a significant Airport \times Group \times Wave interaction, $F(2, 311) = 4.25, p = .015$. Separate *t* tests showed a marginally significant difference between groups at the old airport at Wave 1, $t(104) = 1.88, p = .062$, one-tailed, but not at Waves 2 and 3 ($ts < 1.28$). At the new airport, there was a difference between groups at Wave 3, $t(208) = 2.72, p = .007$, but not at Waves 1

Fig. 2. Mean number of errors on the difficult paragraphs in the reading test as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

Fig. 3. Mean score on the long-term memory task as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

and 2 ($ts < 1.12$). For the number of lines completed, there were no noise effects.

At the old airport, the short-term memory test showed a significant Group \times Wave interaction, $F(2, 203) = 5.97, p = .004$. The poorer short-term memory performance of the noise group recovered to reach the level of the control group's performance at Waves 2 and 3 (see Fig. 4). Separate *t* tests showed tendencies toward more correct responses in the no-noise group than in the noise group at Wave 1, $t(104) = 1.70, p = .092$; the difference was in the opposite direction at Wave 2, $t(104) = 1.63, p = .108$, and there was no difference between groups at Wave 3. At the new airport, there were no differences between the groups across the waves.

Attention

For the embedded-figures task, there were no reliable interactions involving chronic aircraft noise over time.

For the reaction time task, a MANOVA of reaction time and errors together yielded an Airport \times Group \times Wave interaction, $F(4, 179) = 5.58, p = .004$. Performing the task in acute noise or no noise did not qualify this interaction, and there was no main effect of acute noise, $F_s < 1$. Only reaction time, not errors, contributed to the interaction. The aircraft-noise group at the old airport was slower than its control group

Aircraft Noise and Children

Fig. 4. Mean proportion of correct items on the short-term memory task as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

at Wave 2, $t(61) = 2.29, p = .026$, but not at the other waves ($t_s < 1.34$). At the new airport, the aircraft-noise group was slower than the no-aircraft-noise group at Wave 3, $t(121) = 2.09, p = .039$.

Speech Perception

Because of apparatus failure and resulting low n_s , data from Wave 2 on the speech perception task were discarded. As Figure 5 shows, speech perception improved from Wave 1 to Wave 3 at the old airport, but there was no differential improvement between the groups. At the new airport, the onset of aircraft noise seemed to block improvement in auditory discrimination from Wave 1 to Wave 3, as evidenced by the Group \times Wave interaction, $F(3, 150) = 7.63, p = .000$.

Mediation

To probe for mediation, we entered into path analyses (LISREL; Jöreskog & Sörbom, 1996) the difference scores between performance in the last and first measurement waves for the paragraph reading task, the difficult word list, the long-term memory task, the number of lines completed, the short-term memory task, and the speech perception task. The results of these path analyses were straightforward and showed a

Fig. 5. Mean dB-ratio of speech to noise on the speech perception task as a function of airport, noise group, and measurement wave. Error bars show standard errors of the means.

very good fit between data from both airports and one of the models (see Fig. 6). Good fits were indicated by both a high p value ($>.05$) for chi-square and a low value of the root mean square error of approximation ($<.08$; Jöreskog & Sörbom, 1996). In this model, the noise effect on the reading tasks was not mediated by memory or speech perception. For long-term memory, there was a partial mediation by the word-list component of the reading task. For all the other tested variables in different combinations there were no indications of mediating links. The value of N in this analysis was low, mainly because of participants not finishing the difficult reading paragraphs in Wave 1. However, path analyses not including reading, and thus having a higher N , yielded path coefficients between the other variables that were of approximately the same strength as shown in Figure 6.

DISCUSSION

These longitudinal data complement nearly 20 cross-sectional studies showing adverse impacts of aircraft noise on reading in elementary-school children. Moreover, these effects occur prospectively and may be reversible. We have also demonstrated prospective impacts of chronic noise on long-term memory. More work is needed to determine the sensitivity of this effect to the duration of exposure, as well as children's age.

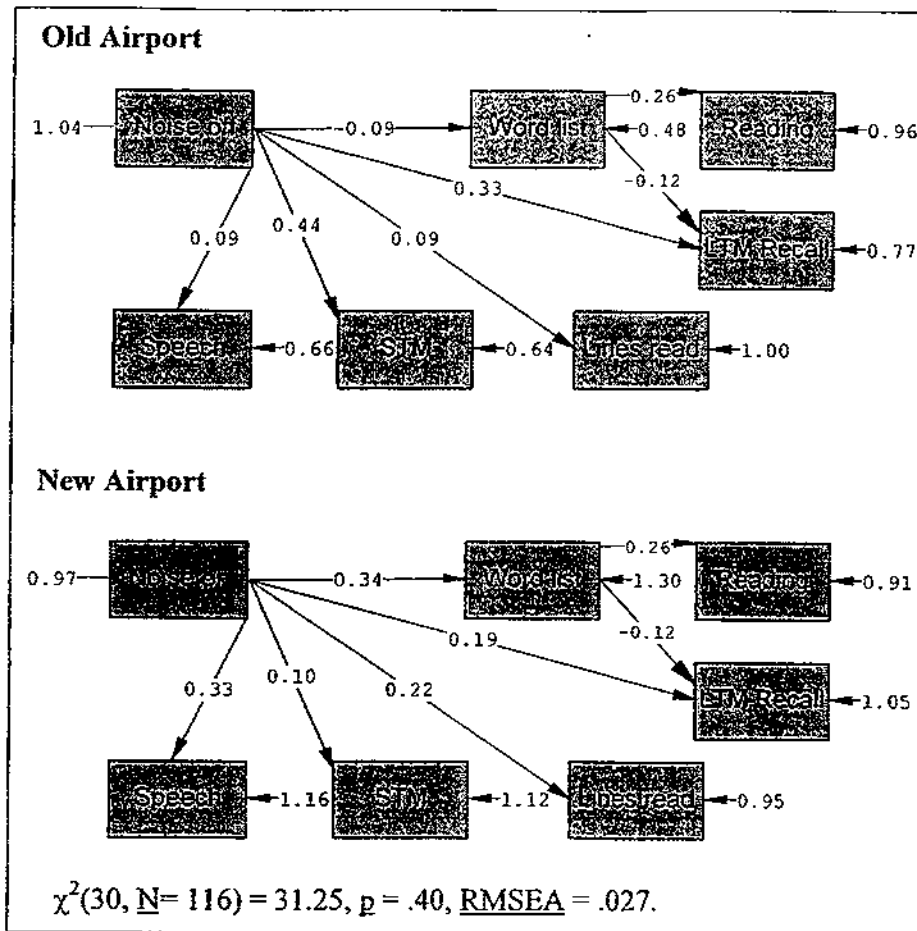

Fig. 6. Model fit (chi-square and root mean square error of approximation, RMSEA) and standardized path coefficients between cognitive measures. The cognitive measures were calculated as difference scores between the last and first measurement waves for the difficult word list ("Word list"), the paragraph reading task ("Reading"), the long-term memory task ("LTM Recall"), the number of lines completed ("Lines read"), the short-term memory task ("STM"), and the speech perception task ("Speech"). The paths from Word list to Reading (0.26) and LTM Recall (-0.12), with values in smaller print, were constrained to be equal at the two airports.

This is also the first study to show prospective impacts of chronic noise on a cognitive process, long-term memory. Weaker evidence suggests noise-induced deficiencies in speech perception and short-term memory.

Reading and long-term memory effects replicated, disappearing when the old airport closed and emerging after the new airport opened. This provides strong causal evidence for the vulnerability of central language processing to noise exposure, and the reversible nature of the impact. Additional research is needed to see whether the adverse noise effects on reading and recall continue over time. Note that at the new airport the negative effects were stronger at Wave 3 than at Wave 2, which suggests a cumulative noise effect.

The speech perception findings warrant further research. Differences in speech perception did not mediate noise effects on reading. The lack of mediation is inconsistent with prior cross-sectional studies (Cohen et al., 1973, 1986; Evans & Maxwell, 1997). The present longitudinal data raise doubts about the validity of inattention, or "tuning out," as an explanatory mechanism for the adverse impacts of noise on reading performance.

Furthermore, although children's reading worsened with cumulative noise exposure at the new airport and recovered following noise cessation at the old airport, speech perception deficits among noise-exposed children at the old airport did not recover. This suggests that speech perception did not mediate the noise effects on reading, a conclusion that is also indicated by the structural equation results. An explanation for this pattern of results may be the developmental timing of the noise exposure. Perhaps noise exposure damages the development of speech perception in different ways during the early and late portions of the reading-acquisition period.

Future research needs to address the importance of both the developmental timing and the duration of noise exposure in determining the effect of noise on reading and cognitive development. Research also needs to sample a wider range of noise levels in order to generate a dose-response function for reading, which would provide additional basic evidence and better inform public policy for noise protection of children.

Acknowledgments—This study was conducted with Staffan Hygge with the National Swedish Institute for Building Research and with Kungl Tekniska Högskolan—Royal Institute of Technology, both in Gävle, Sweden. We are grateful to the families who cooperated with this research. We thank Gerhard Heim, Sylvia von Mackensen, Markus Meis, Gunnar Söderqvist, and Christian Wigren for their dedication to the project. This research was partially supported by the Society for the Psychological Study of Social Issues, the National Institute of Health (R01 HL 4732 01A), the National Institute of Child Health and Human Development (1 F33 HD 08473-01), the Nordic Scientific Group for Noise Effects, the Swedish Environmental Protection Agency, the German Research Foundation (DFG), and the National Swedish Institute for Building Research. The third author was also supported by a DFG Heisenberg Fellowship. We are particularly grateful to Nils Antoni, former director of the National Swedish Institute for Building Research, who efficiently made necessary funds available at the outset of the Munich study.

Nonauditory Effects of Noise on Children: A Critical Review

Gary W. Evans
Cornell University
New York, USA

Stephen J. Lepore
Carnegie Mellon University
USA

Large numbers of children both in the United States and throughout the economically developing world are chronically exposed to high levels of ambient noise. Although a great deal is known about chronic noise exposures and hearing damage, much less is known about the nonauditory effects of chronic ambient noise exposure on children. To estimate the risk of ambient noise exposure to healthy human development, more information about and attention to nonauditory effects such as psychophysiological functioning, motivation, and cognitive processes is needed. This article critically reviews existing research on the nonauditory effects of noise on children; develops several preliminary models of how noise may adversely affect children; and advocates an ecological perspective for a future research agenda.

Keywords: noise, stress, nonauditory effects, health, cognitive

INTRODUCTION

In 1973 nearly 10 million American school children were exposed to ambient noise levels that exceed federal standards for hearing protection in work settings (Environmental Protection Agency, 1974). Recent studies estimate that American children on average are exposed daily to noise levels in the range of 76-80 Leq (unweighted average of decibel levels for 24 hours) (Roche et al., 1982; Schori & McGatha, 1978). To put these figures in perspective, the EPA recommended limit for risk to hearing is 70 Leq daily exposure for children. Since these assessments of childhood noise exposure, there have been marked increases worldwide in the number of children exposed to noise levels loud enough to impair hearing: this is especially true in underdeveloped countries (Evans, 1990; Suter, 1991).

Many *nonauditory* effects of noise on children also have been detected during the past two decades of research. Nonauditory effects of noise refer to impacts not directly related to sound-

induced damage to the auditory system. Non-auditory effects of noise, such as elevated sympathetic nervous system activity or disturbances in attentional processes, are apparent in children exposed to noise levels far below those necessary to induce auditory damage.

Although there is abundant evidence and analysis of the auditory effects of noise on children (Kryter, 1985; Mills, 1975), there has been little systematic, critical analysis of the nonauditory effects of noise exposure among children. This is a critical omission if we are interested in estimating the true risk of noise exposure to healthy human development. The present article critically examines the empirical evidence on the nonauditory effects of noise on children. The work is organized into three general areas of functioning: physiological, motivation, and cognitive. Both conceptual as well as methodological limitations in the extant research are examined.

Physiological Effects of Noise

Work in animal models and in various occupational settings suggests heightened activation of the cardiovascular system among organisms

Table 1. Effects of noise on cardiovascular outcomes

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Brackbill et al. (1982)	HR	1 h white noise for 4 consecutive days. 50 and 75 dBA.	(78 males) ages 1 mon. to 80 yrs.	In infants and 8-year olds, HR decreased as sound levels increased. No other main or interactive effects of noise.
Cohen et al. (1980)	BP	Aircraft. 95 dBA peak.	(262) grades 3-4.	Noisy-school children had higher SBP and DBP than quiet-school children.
Cohen et al. (1981)	BP	Aircraft. 95 dBA peak.	(163) grades 3-4, longitudinal sample.	In the longitudinal attrition sample, there were no effects of noise on BP.
Cohen et al. (1986)	BP	Aircraft. 16 dBA sound reduction in noise-abated classrooms.	(163) grades 3-4, longitudinal sample.	SBP marginally lower and DBP significantly lower in quiet- than noisy-school children. SBP and DBP marginally lower in quiet- than noise-abated school children. No BP differences in children in noisy vs. noise-abated school.
Cohen et al. (1986)	BP	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Noisy-school children had higher BP than quiet-school children if were enrolled for 2 yrs or less. No noise effects on children enrolled more than 2 yrs.
Karsdorf & Klappach (1968)	BP	Traffic and street. 63-84 phon.	(262) grades 7-10.	Children in quiet schools had normal BP; whereas those in moderately- to very-noisy schools had elevated BP, especially among older boys.
Ising et al. (1990)	BP	Low altitude military flights. 125 dBA peak/Leq 68 dBA.	(433) ages 10-13 yrs.	Noise-related increases in SBP and DBP for girls, but not boys. Noise-related HR deceleration in boys and girls, but deceleration only significant in boys.
Karagodina (1969)	BP	Aircraft. 112 dBA peak/Leq 58 dBA.	(unavailable) ages 9-13 yrs.	Noisy-school children had higher BP than quiet-school children.
Roche et al. (1982)	BP	Self-report of exposure to loud noise sources. 80-Leq.	(233) ages 12-14 yrs.	Self-reported noise exposure levels not associated with BP.

Note: HR = heart rate, BP = blood pressure, S = systolic, D = diastolic.

chronically exposed to noise (Kryter, 1985; Smith, in press). As shown in Table 1, several studies have also uncovered evidence of possible linkages between chronic noise exposure and elevated blood pressure among children.

With two exceptions, all of the studies shown in Table 1 report elevations of resting blood pressure among children chronically exposed to noise. The one experimental study (Brackbill et al., 1982) found habituation to noise, which is a well established psychophysiological finding with short-term noise exposures (Glass & Singer, 1972). The extent of blood pressure elevations found from chronic exposure are probably not clinically significant for children during their youth (Voors et al., 1976), but could portend elevations later in life that might be health damaging (Berenson, 1980). To our knowledge,

there have been no long-term follow up studies of children exposed to noise at an early developmental stage. We know essentially nothing about the long-term consequences of early noise exposure on developing cardiovascular systems.

Both of the studies in Table 1 that found nonsignificant correlations between noise exposure and chronic blood pressure levels have methodological limitations. Roche et al. (1982) relied on children's retrospective reports of exposure to noise events (e.g., motorcycle use) during the previous six months. No data were presented on the reliability or validity of these noise estimates. Furthermore, the children monitored did not live near especially high noise sources (e.g., airports). Instead exposure to point noise sources such as machinery was estimated. Finally, resting blood pressure was only estimated

with one reading. On the other hand, this is the only study to examine the association between typical, daily noise exposures and resting blood pressure among children. All other studies have assessed the association between chronic blood pressure and exposure to high noise sources such as airports, roads, or trains. Analyses of the health effects of typical noise exposure for children are needed but with more adequate measurements of both noise exposure and blood pressure.

The second study to find a nonsignificant association between chronic noise exposure and resting blood pressure levels was conducted with children exposed to high levels of noise from an airport. Cohen et al. (1981) found that a difference in blood pressure between children attending noisy versus quiet elementary schools in a cross-sectional analysis did not replicate when reassessed one year later. Attritional analyses suggested that the failed longitudinal replication was caused by emigration of the families of children in noisy areas with the highest levels of blood pressure. Among children attending quiet schools, on the other hand, there was no selective attrition related to blood pressure levels.

Unlike other studies listed in Table 1, the three studies by Cohen and colleagues (Cohen et al., 1980; 1981; 1986) include statistical controls (e.g., social class, education) to counter potential third variable explanations of the associations uncovered between noise exposure and chronic levels of blood pressure. However, none of the studies is prospective, nor do any show a dose response relation between noise and blood pressure. Furthermore, all of the extant studies have relied upon gross indices of noise exposure - typically peak readings measured at schools.

Noise in the fetal and neonatal environment may be particularly harmful to fetuses and newborns because they are in a period of great organismic plasticity. It is well established that environmental sounds and vibration influence physiological and behavioral responses in the fetus (Pikus, 1991). There are contradictory data on the relations between ambient noise exposure and birth weight (for reviews see Pikus, 1991; Smith, in press) but little or no definitive evidence for teratological effects of chronic noise exposure (Edmonds et al., 1979; Meyer et al., 1989). Nonetheless, it is critical for more thorough and extended investigation of the potential impacts of routine modern medical procedures such as ultrasound monitoring or

placement of premature babies in intensive care nurseries with extremely noisy equipment (Gottfried et al., 1981; Lawson et al., 1977).

Summary

Residing or attending school near a major noise source is associated with elevated blood pressure. More research is clearly called for, especially tracking children before, during, and after exposure to noisy environments. All evidence to date is correlational and even though some studies have included good controls, stronger, quasi-experimental designs are needed to firmly tie noise to the etiology of cardiovascular changes in children. The degree of blood pressure elevations is small, on the order of 4-8 mm of mercury, but these elevations do not appear to habituate with continued exposure (cf., Cohen et al., 1986). The clinical significance of such changes in childhood blood pressure is difficult to determine. The ranges of blood pressure among noise-exposed children are within normal levels and do not suggest hypertension. On the other hand, elevations in blood pressure among children appear to track into adulthood (Beren-son, 1980), increasing the potential risk for cardiovascular disease. It would also be of value to examine neuroendocrine makers of stress (e.g., cortisol) that have been implicated in the casual pathways between stressors and cardiovascular outcomes.

Emotional/Motivational Effects of Noise

The uncontrollability of chronic noise exposure may affect children's emotional and motivational states. When organisms are exposed to repeated, uncontrollable events, learned helplessness can occur (Abramson et al., 1978; Seligman, 1975). Learned helplessness means the organism learns that the outcomes of its behavior are independent of its responses. Learned helplessness is manifested as a lack of effort or responsiveness to environmental stimuli and challenges. Uncontrollable noise has been shown to induce helplessness in adults (Hiroto, 1974; Hiroto & Seligman, 1975; Krantz et al., 1974). Moreover, adults immediately following exposure to uncontrollable noise are less likely to persist on difficult or challenging aftereffect puzzles than their counterparts with prior exposure to controllable noise (Cohen, 1980; Glass & Singer, 1972).

Overall, though, very little is known about the

Table 2. Effects of noise on motivation (learned helplessness)

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Cohen et al. (1980)	Performance on moderately difficult puzzle after pretreatment with insoluble or soluble puzzle.	Aircraft. 95 dBA peak.	(262) grades 3-4.	Noisy-school children failed more on pretreatment soluble puzzle and difficult test puzzle, and were more likely to give up on difficult puzzle, than quiet-school children. There was a nonsignificant trend suggesting that longer exposure to a noisy school was associated with greater time to complete difficult puzzle.
Cohen et al. (1981)	Performance on moderately difficult puzzle.	Aircraft. 95 dBA peak.	(163) grades 3-4, longitudinal sample.	Noisy-school children were more likely to fail at the test puzzle and to take longer to solve the puzzle than quiet-school children. No noise effect on rate of giving up.
Cohen et al. (1981)	Performance on moderately difficult puzzle.	Aircraft. 16 dBA sound reduction in noise-abated classrooms.	(163) grades 3-4, longitudinal sample.	Sound attenuation improved children's performance on the original test puzzle.
Cohen et al. (1986)	Performance on moderately difficult puzzle.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Noisy-school children failed difficult puzzle more frequently than did quiet-school children.
Cohen et al. (1986)	Choice task.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Noisy-school children more likely than quiet-school children to give choice of reward to experimenter.
Moch-Sibony (1984)	Rosenzweig frustration tolerance test.	Aircraft. 29 vs 54 SIL.	(80) kindergarten.	Noise-related decreases in frustration tolerance.
Wachs (1987)	Observer ratings of mastery-oriented play behavior.	Ratings of noise: 1 = normal level voices in home for 15 min. period to 4 = noisy level voices in home for more than half 15 min. period.	(88) 12 mon.	Less mastery-oriented play behavior in noisier homes.

Note: SIL = speech interference level.

relations between chronic exposure to environmental stressors such as noise and the induction of helplessness in human beings. Community surveys of noise annoyance frequently note that while annoyance is common, complaints or other actions to intervene are rare (Evans & Tafalla, 1987). Most residents who are annoyed by noise report feeling unable or helpless to alter the situation (Jue et al., 1984). The small minority who do complain or take other actions report feeling greater self-efficacy to cope with the noise (Jue et al., 1984).

As shown in Table 2, a few studies have examined the effects of noise on children's motivational states. The significant relations between noise exposure and motivational deficits in one cross-sectional study (Cohen et al., 1980) were replicated both in a longitudinal study (Cohen et al., 1981) and in a second, cross-sectional study

(Cohen et al., 1986). Higher noise exposure in children has been associated with reduced persistence on challenging puzzles and greater abdication of choice over rewards (see Table 2). Perhaps the most persuasive data of reduced motivation in an achievement related situation is Cohen et al.'s (1980) findings on giving up. Not only were children from noisy schools less likely to solve a challenging puzzle within a four minute time period, a substantially greater proportion of them (15%) simply gave up before the allotted time had elapsed, often remarking that they couldn't do the task, in comparison to 2% of their quiet school counterparts who gave up.

Of additional interest, teachers from schools located in noisy settings report more difficulties motivating students to perform than do teachers from relatively quiet schools (Crook & Langdon, 1974; Kyzar, 1977; Moch-Sibony, 1984).

Even very young children appear to be less motivated to engage in object mastery or control over their environment, after prolonged exposure to noise. For example, 12-month-old infants living in noisier households tended to engage in less effective, mastery-oriented interactions with toys in their homes than did children from relatively quiet homes (Wachs, 1987).

Learned helplessness is more apt to occur when individuals make stable, personological attributions (e.g., ability) rather than ascribe global or temporary reasons (e.g., bad luck, poor effort) for their failures (Abramson et al., 1974; Silver et al., 1982). No research on noise and motivation has examined these underlying attributional processes. Future research should also directly manipulate contingencies in a task (e.g., provision of insoluble puzzles) and then examine differences in tendencies to become helpless along with attributional measures, as a function of chronic noise exposure. In addition, researchers should examine the possible mental health consequences of noise-related learned helplessness. If noise heightens vulnerability to helplessness, then it is reasonable to suspect possible connections between chronic noise exposure and certain psychological problems in children. In one exploratory study, Wachs (1988) found a positive association between noise levels in the home and adaptability, but noise was unrelated to several other indices of temperament. In another study, a composite index of noise and confusion/clutter in the home was linked to difficulty in care requirements for 18-month-old children, although not for 12-month or 24-month-olds (Wachs, 1989).

Summary

Brief exposures to uncontrollable noise are capable of inducing learned helplessness in adults. Chronic residential exposure to noise also appears to be associated with feelings of helplessness among adults living nearby airports. Although the evidence is scant, there are suggestive findings indicating that children chronically exposed to ambient noise sources may be more vulnerable to learned helplessness. Children attending schools in airport flight paths are less likely to solve or persist in attempting to solve challenging puzzles. They are also more likely to abdicate choice over a reward to an adult rather than exercising the choice option themselves. Teachers of children in noisy schools also report, on average, greater difficulties in

motivating children in their school work. Noise in the home may be associated with mastery motivation in very young children. In addition to the small number of studies, all of which are correlational, another drawback to this area of work has been a lack of systematic integration of more sophisticated developmental paradigms for the measurement of motivational deficits in children. The potential pathways among chronic noise exposure, helplessness, and psychological health warrant further research.

Cognitive Effects of Noise

Research on the cognitive effects of noise exposure on children has received the most attention from researchers. This area of research can be subdivided into three subtopics: (i) attention and perception, (ii) memory, and (iii) intellectual achievement.

Attention and perception

The cognitive ability to perceive order and contingency in the environment presumably depends on some modicum of sustained attention to event sequences as they unfold. The interruptive, distracting effects of high ambient noise levels might directly affect the young child's ability to sustain voluntary attention or to concentrate (Heft, 1985).

As shown in Table 3, studies by Karsdorf and Klappach (1968), Kyzar (1977) and by Moch-Sibony (1984) have revealed deficits in standardized measures of sustained attention among children chronically exposed to noise. The standardized tests involve searching for target geometric stimuli from among fields of similar objects. In addition, teachers report that children in noisy schools tend to have more difficulties in concentrating in comparison to children from relatively quieter schools (Crook & Langdon, 1974; Ko, 1979; Kryter, 1985; Kyzar, 1977).

Cognitive studies on children with variable exposures to chronic noise sources also indicate possible decrements in visual attention (see Table 3). Children from noisy homes took longer to locate target pictorial stimuli within an array of pictures than did children from relatively quiet homes (Heft, 1979). Children attending daycare centers located near train tracks performed marginally more poorly on a visual search task

Table 3. Effects of noise on attention

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Crook & Langdon (1971)	Teachers' reports of concentration.	Aircraft. 75 dBA peak.	(76 teachers) primary and secondary.	Teachers in noisy schools reported more concentration problems in students than did those in quieter schools.
Hambrick-Dixon (1986)	Cross-out letters in quiet or noise.	Train. 108 dBA peak.	(109 black) ages 4-6 yrs.	Children from noisy daycare performed task marginally worse than children from quiet daycare.
Hambrick-Dixon (1988)	Visual stimulus detection with verbal or key press response.	Train. 108 dBA peak.	(102 black) ages 5-7 yrs.	Interaction between location of daycare, response mode, exposure duration, and sex: On key response, girls in noisy daycare less than 2 yrs made more errors than girls in quieter daycare less than 2 yrs. On verbal response, girls in noisy daycare more than 2 yrs made more errors than girls in quiet daycare more than 2 yrs. No differences in performance of boys in any condition.
Heft (1979)	Response latency in visual search.	Noise ratings: 1 = low to 7 = high.	(94) ages 4-7 yrs.	Higher household-noise level associated with longer response latency.
Karsdorf & Klappach (1968)	Errors and latency on Bourbon test.	Traffic and street. 63-84 phon.	(262) grades 7-10.	Noisy-school students had longer response latency and more errors than quiet-school students.
Ko (1979)	Teachers' reports of concentration.	Aircraft. 105 dBA peak.	(2100 teachers) primary and secondary.	Teachers in noisy schools reported more concentration problems in students than did those in quieter schools.
Kyzar (1977)	Minnesota clerical test.	Traffic and street. 62-94 dBA.	(56) elementary school.	Noise-related deficits in clerical-type task.
Kryter (1985)	Teachers' reports of concentration.	Aircraft. 87 dBA peak.	unavailable.	Teachers in noisy schools reported more concentration problems in students than did those in quieter schools.
Moch-Sibony (1984)	Zazzo sustained attention task.	Aircraft. 29-54 SIL.	(80) kindergarten.	Noisy-school children had poorer sustained attention than did quiet-school children.
Acute noise				
Zentall & Shaw (1980)	Visual search for letters.	Taped class noise from free time (71 dBA) and work time (57 dBA).	(36) grade 2 (hyperactive and non-hyperactive controls).	Noise x Hyperactivity interaction: Hyperactive children made fewer commission errors in low than in high noise conditions; non-hyperactive children unaffected by noise.

Note: SIL = speech interference level.

than did children from relatively quiet daycare centers (Hambrick-Dixon, 1986). In a subsequent study, Hambrick-Dixon (1988) uncovered a more complex relation between chronic noise exposure and attention, utilizing a vigilance task: Gender, exposure duration to train noise at the daycare center, and the response mode for the task (naming versus pressing a key) moderated the association between noise and performance.

Unfortunately, several of the sustained attention and noise studies suffer from methodological shortcomings. The Kyzar (1977) and Karsdorf and Klappach (1968) studies have inadequate controls

for sociodemographic factors. Furthermore, all of the studies are cross-sectional and only the Moch-Sibony (1984) study carefully screened children for normal hearing. The Heft (1979) study relied upon observer ratings of home noise levels, no actual noise measurements were taken.

The Hambrick-Dixon (1988) results are particularly complex and difficult to interpret. One possible explanation for the inconsistency between her results and those of other researchers is that she measured the ability of children to detect a visual signal using tachistoscopic presentation times (100 msec). Thus rather than

Table 4. Effects of noise on auditory discrimination/speech perception

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Cohen et al. (1973)	WAD	Traffic and street. 55-66 dBA.	(54) grades 2-5.	Noise associated with poorer auditory discrimination.
Cohen et al. (1980)	WAD	Aircraft. 95 dBA peak.	(262) grades 3-4.	No effects of noise on auditory discrimination.
Cohen et al. (1986)	WAD	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	No effects of noise on auditory discrimination.
Moch-Sibony (1984)	MP	Aircraft. 29 vs 54 SIL.	(80) kindergarten.	Noise associated with poorer auditory discrimination.
Acute noise				
Blue & Vergason (1975)	GFW	Recorded sounds (unspecified). 55 dBA.	(34) grades 1,3.	Race x Noise interaction: Black children's performance affected more negatively by noise than was white children's performance.
Nober & Nober (1975)	WAD	Recording of classroom noise vs ambient noise. 39.5-64.7 dBA.	(39) ages 5-7 yrs (healthy control, retarded, and speech-deficit).	Fewer errors when tested in quiet vs. normal classroom noise levels. Control and retarded children performed worse in noise than in quiet; speech-deficit group performed worse in noise than in quiet, but the effect was not significant.
McCroskey & Devens (1977)	WAD	Classroom noise recording. 4 dBA above ambient classroom noise	Unavailable.	Noise associated with decrements in auditory discrimination.
Glenn et al. (1978)	Speech discrimination	Recorded hospital sounds. 75 dB SPC (typical for hospitals).	(21) ages 9-14 yrs (institutionalized MR).	Noise mask significantly degraded speech discrimination.
Laraway (1985)	Digit discrimination	Intermittent white noise. 80 dB SPC.	(46) ages 5-21 yrs (CP, healthy controls).	Noise mask degraded performance of CP children but not controls. Noise effects greatest in younger (< 7 yrs) children.
Laskey & Tobin (1973)	Message comprehension	Speech and white noise. 74 dB SPC.	(22) ages 6-8 yrs (possible LD, non-LD controls).	Speech, but not white noise, interfered with auditory message comprehension in LD children. Control children unaffected by noise.

Note: WAD = Wepman auditory discrimination test, GFW = Goldman-Fristoe-Woodcock auditory discrimination task, MP = Massiot Phillips auditory discrimination test, SIL = speech interference level, LD = learning disabled, CP = cerebral-palsied, MR = mentally retarded.

measuring sustained visual attention, Hambrick-Dixon probably measured signal detectability.

As expected given the physical properties of noise, considerable attention has been given to auditory information processing among children exposed to chronic or acute noise sources. One of the cognitive strategies that children may learn in order to adapt to the distracting properties of chronic noise is to filter or tune out unwanted auditory stimuli. The tendency of children in noisy environments to tune out noise may become overgeneralized, such that various types of acoustic stimuli, including speech, are not attended to carefully (Deutsch, 1964). In a direct

test of the tuning out hypothesis, Cohen et al. (1973) compared the ability of children living in quiet and noisy apartments (proximity to a freeway) within the same building to discriminate between similar sounds under quiet conditions. Cohen et al. (1973) as well as Moch-Sibony (1984) found an association between chronic noise exposure and auditory discrimination (see Table 4). Both of these studies had good controls for socioeconomic status, and pre-screened children for hearing loss. Moreover, Cohen et al. (1973) showed that with longer exposure durations, the association between noise and deficits in auditory discrimination became stronger.

Table 5. Effects of noise on resistance to auditory distractors

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Cohen et al. (1980)	Cross-out letters in ambient or distracting (story recording) condition.	Aircraft. 95 dBA peak.	(262) grades 3-4.	Noise × Month enrolled interaction: with less than 2 yrs enrollment, noisy-school children performed better than quiet-school children under distraction. Between 2-4 yrs enrollment, no noise effects. With more than 4 yrs enrollment, noisy-school children performed worse than quiet-school children.
Cohen et al. (1981)	Cross-out letters in ambient or distracting condition.	Aircraft. 95 dBA peak.	(163) grades 3-4, longitudinal sample.	With 2-4 years enrollment, noisy-school children were less distracted than quiet-school children. With more than 4 yrs enrollment, performance was nearly the same across conditions.
Cohen et al. (1986)	Cross-out letters in ambient or distracting condition.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	Children attending noisy schools for 2-4 yrs were less distracted than their quiet-school counterparts. However, after 4 yrs enrollment, performance was nearly the same across conditions.
Cohen et al. (1981)	Cross-out letters in ambient or distracting condition.	Aircraft. 16 dBA reduction in noise-abated classrooms.	(163) grades 3-4, longitudinal sample.	No effects of noise abatement on distractibility.
Hambrick-Dixon (1986)	Weschler IQ task and match animals with color disks in quiet or noise conditions.	Train. 108 dBA peak.	(109 black) ages 4-6 yrs.	Children from noisy daycare performed better in noise than in quiet conditions. The opposite was found for children from quiet daycare centers.
Heft (1979)	Figure discrimination in matching task in quiet or noise.	Story reading. Noise ratings: 1=low to 7=high.	(94) ages 4-7 yrs.	Auditory distraction had less of a negative effect on children from noisy homes than on children from quiet homes.
Acute noise				
Tumure (1970)	Performance and glances away from a visual discrimination task.	Recording of child songs/stories. 60 dBA.	(30) ages 5.5, 6.5, 7.5 yrs.	No noise effects on glances, but performance worse in noisy than in quiet conditions.
Steinkamp (1980)	Multiple perceptual and cognitive tasks.	Classroom sounds and gadgets. Ambient noise.	(24) ages 6-8 yrs (hyperactive, non-hyperactive controls).	Classroom noise and distracting visual materials caused deficits on most tasks. No interaction with hyperactivity.

In two subsequent studies, Cohen et al. (1980; 1986) were unable to replicate these findings on noise and auditory discrimination using a different noise source (aircraft as opposed to traffic). The traffic noise study (Cohen et al., 1973) also drew primarily from working class families; whereas the airport study was conducted in a poverty area. Using a different auditory discrimination task, however, did reveal deficiencies in auditory discrimination in children chronically exposed to noise from airports (Cohen et al., 1986). Children were presented a constant signal (man reading a story) superimposed against four different white noise backgrounds. The task was

to choose the optimum signal to noise ratio. Children who attended noisy schools for longer periods were significantly poorer at this signal to noise discrimination task (see Table 4).

Not surprisingly, the acute noise experimental studies in Table 4 indicate that children have difficulty with auditory discrimination during acute noise exposure (Blue & Vergason, 1975; Glenn et al., 1978; Laraway, 1985; Nober & Nober, 1973). Thus noise can directly interfere with children's ability to discriminate between meaningful auditory stimuli. Noise, particularly irrelevant speech, also interferes with comprehen-

sion of spoken language (Glenn et al., 1978; Laraway, 1985; Lasky & Tobin, 1973). The Glenn et al. (1978) data are noteworthy because the researchers used simulated recordings of an institutional setting for the mentally retarded as their noise 'mask'. Typical, ambient levels from the institution were sufficient to produce marked deficits in discriminating speech sounds among mentally retarded children.

Although there are clear overall trends showing that concurrent noise can mask auditory discrimination, as well as speech, there may be individual differences in these effects. Blue and Vergason (1975) found racial differences in auditory discrimination with black children being more adversely affected than white children by concurrent noise. This study was conducted in the Southeastern United States and may not have controlled for the dialect used in stimulus materials. Laraway (1985) reported that only cerebral palsied children were adversely affected by a noise mask in a task in which children were asked to repeat auditorily presented digits. Lasky and Tobin (1973) revealed that only children with suspected learning disabilities had difficulties in tracking an auditory signal against a background of competing, irrelevant speech. The latter study also showed that speech, but not white noise of a similar volume, interfered with message comprehension.

An interesting and provocative question raised by Deutsch's original hypothesis and some of the subsequent empirical work is whether children chronically exposed to noise become so adept at filtering out noise, that they become resistant to its distracting properties. A number of studies shown in Table 5 present suggestive evidence in support of this hypothesis of differential resistance to noise distractors. However, the data are complex.

Kindergarten children from noisy homes were less distracted by irrelevant speech during a visual discrimination task than those from quiet homes (Heft, 1979). In this task, children selected one of several figures that correctly matched a standard figure. Cohen and colleagues (1980) found a similar pattern of results, but only for elementary students exposed to aircraft noise for two years or less. For those exposed longer, auditory distraction during a visual search task (crossing out e's in a text above reading level of the child) interfered more with the performance of noisy-

school children than it did for quiet-school children. This effect was also replicated in a different sample (Cohen et al., 1986). Hambrick-Dixon (1986) uncovered an even more complex pattern of data on a visual coding task among very young children. In this task preschool children placed colored discs next to animal drawings according to an initial set of model comparisons. For children from noisy daycare centers, performance on this task was better under noisy testing conditions than quiet ones; whereas for children from quiet daycare centers, performance was superior during quiet testing conditions than under noisy ones.

Thus, although there is some evidence that children chronically exposed to noise are less distractable by auditory stimuli during a task, with very long exposure (4+ years), they appear to lose this advantage over non-noise-exposed children. Children exposed for short periods of time to chronic noise, may be able to gate out auditory distractors more effectively during tasks; whereas children exposed for long periods of time, may lose this gating ability. This could occur because despite sustained efforts to gate out unwanted sounds, children learn that this coping strategy is ultimately ineffective since the noise remains as a potent distractor.

The type of task, type of noise, and some individual difference variables also may influence whether concurrent auditory stimuli are distracting during task performance. For example, although both Heft (1979) and Cohen et al. (1980; 1986) found that concurrent speech distracted children during a visual search task (finding target objects in a matrix, crossing out target letters in text, respectively), Hambrick-Dixon (1986) had no main effect of a distractor (background noise of a daycare free play period) on performance of a visual matching task (placement of colored discs next to animal drawings). Turnure (1970) found a distracting effect of speech on school children's performance on a visual discrimination task (choosing the odd geometric shape out of three stimuli). However behavioral manifestation of distraction (glancing up) was not observed. Zentall and Shaw (1980) found that classroom noise recordings did not affect a visual letter search task for normal children and degraded performance for hyperactive, elementary-aged children. Finally, Steinkampf (1980) found that the combination of recorded classroom sounds

Table 6. Effects of noise on memory

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Hambrick-Dixon (1986)	Serial, incidental, visual, paired-associates learning.	Train. 108 dBA peak.	(109 black) ages 4-6 yrs.	No noise effects.
Heft (1979)	Incidental memory of visual stimuli.	Noise ratings: 1 = low to 7 = high.	(94) ages 4-7 yrs.	Higher household noise level associated with poorer incidental memory.
Acute noise				
Fenton et al. (1974)	4 number digit-span.	White noise. 22-72 dBA.	(10 male) ages 9-11 yrs (LD and non-LD).	More errors made in the high noise than in the low noise conditions.
Hygge (1993)	Recall and recognition of reading passage.	Recorded simulations of aircraft, train, traffic, and verbal noise. 66-76 dBA.	(417) ages 12-14 yrs.	Within-subjects analyses revealed a marginal Noise x Source interaction: recall on difficult questions was lower among children in aircraft and traffic noise conditions than in control conditions; no differences in recall in train and verbal noise conditions relative to control condition. Between-subjects analyses also revealed a Noise x Source interaction: recall on difficult questions was lower among children in aircraft noise conditions than in controls; other noise sources did not affect recall. No noise effects on recognition task. Individual differences in learning ability did not moderate noise effects.
Johansson (1983)	Paired-associates learning and letter memory.	White noise. 51 dBA continuous; 55-78 dBA intermittent.	(66) age 10 yrs.	No noise effects.

Note: LD = learning disabled.

played at normal volume and the presence of interesting gadgets were distracting for several tasks among normal and hyperactive boys. Because the latter study did not separate ambient noise from visual distractors, the specific effects of noise cannot be determined.

It is difficult to discern any clear patterns in the above findings on acute, concurrent noise and distraction among children. Speech, as opposed to background noise (e.g., recordings of classroom noise), may be more distracting during task performance. Unfortunately since no studies have used the same task with different aged children, we cannot infer any developmental trends from the data. However it is noteworthy that studies showing no effects tested the youngest children.

Summary

Children chronically exposed to noise may suffer from attentional deficits. Although suggestive,

the work in this area suffers from sufficient methodological flaws (e.g., controls for SES) to prohibit definitive conclusions. Children chronically exposed to noise develop cognitive strategies to cope with the interruptive, distracting influence of noise. Some data suggest that children learn to ignore or tune out auditory stimuli if they have been chronically exposed to noise. At least during the first few years of exposure, children from noisy residential areas appear to be more resistant to acute auditory distractors, presumably because of their enhanced ability to tune out auditory stimuli. These same children may suffer deficits in auditory discrimination. Acute noise distracts children during cognitive task performance, especially when the distractors contain meaningful speech. These acute auditory distraction effects may be more problematic for certain subgroups of children, especially those with some pre-existing cognitive deficits. More research, particularly on groups potentially at risk should be a high priority.

Memory

The noise and memory literature on children (Table 6) is sparse but generally in agreement with the adult literature (Cohen et al., 1986; Smith, in press). There appears to be little or no effects of noise on simple memory tasks from chronic exposure (Hambrick-Dixon, 1986) or acute exposure (Johansson, 1983). However, if sufficient processing demands are placed upon memory, deficits begin to appear in children exposed to noise (Fenton et al., 1974; Hygge, 1993).

Hygge's (1993) experimental findings (see Table 6) are interesting because he compared relatively easy and difficult memory tasks under quiet and noisy conditions, finding that only the difficult tasks were sensitive to noise exposure. Heft's (1979) incidental memory deficits are also noteworthy because they fit with a typical noise and memory finding in adults. The adult incidental memory studies have been interpreted as indicative of attention narrowing or focusing on dominant stimuli (Cohen et al., 1986). Attention narrowing appears to be common under arousing conditions in general (Broadbent, 1971) and under noise specifically (Hockey, 1979). Greater attention to more central cues could lead to poorer encoding of more peripheral material.

Summary

Although there is little research on children's memory under chronic or acute noise conditions, the data are generally in accord with the adult literature on the subject. Noise exposure has little if any effect on children's short term or working memory. Memory tasks that put especially demanding loads on working memory, however, may show some deficits. Narrowing of attention to more central cues under noise may cause poorer memory for incidental information. The potential role of attentional processes in noise-related memory effects warrants further scrutiny.

Intellectual Achievement

Given the reasonable possibility that chronic noise exposure interferes with auditory discrimination and attentional mechanisms, it is not surprising that several researchers have uncovered evidence linking noise exposure with deficits in reading. It is important to note at the onset that unlike chronic effects of noise on cognition, studies of reading and achievement confound chronic and acute noise exposure since they all have relied

upon archival records of achievement tests. As indicated in Table 7, however, the handful of studies of acute noise on intellectual achievement find few if any negative effects. This suggests, indirectly, that the community noise and achievement findings are probably caused by chronic and not acute exposure.

Two clusters of chronic noise associations with intellectual achievement are shown in Table 7. The first group of studies, conducted primarily by Wachs and colleagues, have explored the impacts of early exposure to noise in the home on infants and toddlers. Their work in general finds positive evidence that noise can interfere with normal cognitive development. The findings have been replicated and extended in longitudinal studies (see Wachs & Gruen, 1982, for an overview of this research program). Measurements of cognitive development affected by noise include mental representations of objects, use of objects as tools to achieve goals, and relating words to objects.

One major weakness in Wach's and other research on noise and young children (e.g., Heft, 1979) is reliance on observer ratings of noise exposure rather than actual measurement of physical sound levels. Recently, however Wachs (1988) has validated this measurement approach against decibel meter readings. Another finding that indicates that the effects are due to noise is that access to a secluded quiet room or shelter within the home largely ameliorates the associations between noise ratings and measures of cognitive development (Wachs & Gruen, 1982). Micheison (1968) has found the same buffering effect of a stimulus shelter with home noise levels on elementary school aged children's reading ability. These data on buffering effects of quiet, secluded study spaces in noisy homes raise the possibility, however, that some of the apparent effects of residential noise exposure on cognitive development could be due to residential crowding. It is obviously difficult to disentangle the ecological covariation between these two environmental conditions. Moreover, both of them appear to be associated with deficits in reading acquisition in young children (Evans et al., 1990).

The second group of studies in Table 7, has examined the association between chronic noise exposure at school and/or home with standardized measures of reading and other intellectual achievement tests. With two exceptions, the data

Table 7. Effects of noise on intellectual achievement

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Chronic noise				
Bronzaft (1981)	Reading.	Train. 6-8 dBA sound reduction in noisy classrooms.	(955) grades 2-6.	After sound reduction with insulation on noisy side of school, students' reading scores on noisy side of school were equivalent to those of students on quiet side of school. In the year before insulation, students on noisy side of school had worse reading scores than students on quiet side of school.
Bronzaft & McCarthy (1975)	Reading.	Train. 59-89 dBA.	(161) grades 2, 4, 6.	Students' reading scores lower on noisy side of school than on quiet side, especially in higher grades.
Cohen et al. (1973)	Reading.	Traffic and street. 55-66 dBA.	(54) grades 2-5.	Noise associated with greater reading deficits in children living in apartments for 4 or more years.
Cohen et al. (1980)	Reading and math.	Aircraft. 95 dBA peak.	(262) grades 3-4.	No noise effects.
Cohen et al. (1981)	Reading and math.	Aircraft. 95 dBA peak.	(163) grade 3-4, longitudinal.	No noise effects.
Cohen et al. (1981)	Reading and math.	Aircraft. 16 dBA sound reduction in noise-abated classrooms.	(163) grade 3-4, cross-sectional.	Noise abatement results in 3rd grade only. Third graders in noise-abated classrooms performed better in math than 3rd graders in non-abated classrooms; 3rd graders in noise-abated classrooms also performed better in reading, but not significantly so.
Cohen et al. (1986)	Reading and math.	Aircraft. 95 dBA peak.	(165) grade 3, new sample.	No noise effects.
Gottfried & Gottfried (1984)	BSID, OP, MS, TELD	Noise ratings: 1 = normal level voices in home for 15 min. period to 4 = noise level voices in home for more than half 15 min. period.	(130) 12 mon. infants tested every 6 mon. up to 42 mon.	Higher household noise associated with lower scores on OP at 12-18 mon., on TELD at 39 mon., on BSID at 18 mon., and on MS scores at 42 mon.
Green et al. (1982)	Percent reading below grade level.	Aircraft. 96.2 dBA peak.	(8,240) grades 2-6.	Greater percentage of noisy-school children read below grade level. Effects strongest in higher grades.
Lukas et al. (1981)	Reading and math.	Traffic and street. 70 dBA peak.	(2500) grades 3,6 (100 classes sampled).	Reading scores lower for 3rd and 6th graders in noisier classes. Math scores lower in students in noisier 3rd grade classes, but higher in 6th grade students in noisier classes.
		Ambient classroom and community. 45-75 dBA.		Inverse correlations between community noise and math and reading scores were similar to but less consistent than those between classroom noise and math and reading scores. There also was a synergistic effect of home and school noise on reading.

Table 7. *Continued*

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Wachs et al. (1971)	IPDS	Noise ratings: 1 = normal level voices in home for 15 min. period to 4 = noise level voices in home for more than half 15 min. period.	(102) ages 7, 11, 15, 18, 22 mon.	Higher household noise associated with lower IPDS scores.
Wachs (1978)	SB	Ratings of noise: same as Wachs et al. (1971).	(23) ages 2-3 yrs, longitudinal.	Higher household noise associated with poorer SB performance in boys, no significant effect in girls.
Wachs (1979)	IPDS	Ratings of noise: same as Wachs et al. (1971).	(31) ages 2-3 yrs, longitudinal.	Higher household noise associated with lower IPDS scores in boys and higher IPDS scores in girls.
Wachs & Gandour (1983)	IPDS	Ratings of noise: same as Wachs et al. (1971).	(100) ages 7, 11, 15, 18, 22 mon.	Higher levels of household noise associated with lower IPDS scores, particularly in fussy and irritable infants.
Michelson (1968)	Language, spelling, and math.	Home environment ratings. Scale unavailable.	(710) grades 1-5.	Noise associated with language and spelling difficulties. Noise not associated with math achievement.
Maser et al. (1978)	Reading and math.	Aircraft. 90 dBA peak.	(1917) grades 3, 5, 7, 10.	Noise associated with reading and math deficits in 7th and 10th graders, but only marginal effects on 5th graders. Children with lower aptitudes were most adversely affected by noise.
Acute noise				
Christie & Glickman (1980)	SPM	Recorded classroom noise. 40 and 70 dBA.	(156) grades 1, 3, 5.	Noise × Sex interaction: Boys performed better in noisy than in quiet conditions; girls performed better in quiet than in noisy conditions.
Johansson (1983)	Reading and math.	White noise. 51 dBA continuous, and 55-78 dBA intermittent.	(66) age 10 yrs.	Noise × Intelligence interaction on multiplication and reading performance. Above-average intelligence children solved more multiplication problems in noise than in quiet; below-average intelligence children showed the opposite trend, but noise effects were not significant. Below-average intelligence children tended to have poorer reading speed under noise; there was little difference in reading performance between noise groups with above-average intelligence.
Kassinove (1972)	Math.	Recorded child stories and music. 70-80 dBA.	(80) grades 3,6.	No noise effects on response latency, accuracy, or time-out from task.
Slater (1968)	Reading and math.	Ambient classroom noise, music, stomping and banging, tractor-mower, or quiet crossed with taped white noise. 45-90 dBA and 50-80 dBA white noise.	(263) grade 7.	No noise effects on speed or accuracy.

Table 7. *Continued*

Author(s)	Outcome	Noise Source/Level	Sample Population (n)	Basic Result
Weinstein & Weinstein (1979)	Reading.	Classroom: Ambient noise levels during early (noisy) and late (quiet) time of day. 47-60 dBA.	(60) grade 4.	No noise effects.
Zentall & Shaw (1980)	Math.	Taped noise from 2nd grade class. 64 and 69 dBA.	(48) grade 2 (hyperactive, normal controls).	Noise × Hyperactivity interaction: Hyperactive children performed marginally worse in high noise than in low noise; non-hyperactive children performed worse in low noise than in high noise conditions.

Note: BS = Bayley scales of infant development, OP = object permanence scale, MS = McCarthy scales of children's abilities, TELD = test of early language development, IPDS = Piagetian-type measure of infant psychological development, SD = Stanford-Binet test of intelligence, SPM = standard progressive matrix test.

converge on the conclusion of a relation between community noise exposure and reading ability. Several of the studies have good controls for sociodemographic characteristics in the samples and some have screened out children with auditory deficits. Moreover, Green et al. (1982) found a dose response function between noise exposure and reading deficits. Furthermore, the effects in the Bronzaft studies (Bronzaft, 1981; Bronzaft & McCarthy, 1975) cannot be attributed to self-selection. Children were not assigned in any systematic manner to classrooms on the noisy or quiet side of a building located next to elevated train tracks. On the other hand, all of the studies except for Bronzaft (1981) and Cohen et al. (1981) are cross-sectional and neither of these longitudinal studies are prospective. The Bronzaft (1981) findings are particularly important because they indicate that classrooms on the side of an elementary school near elevated train tracks that previously had lower reading scores in comparison to classrooms on the opposite side of the building (Bronzaft & McCarthy, 1975) no longer differed in reading scores following noise insulation in the schools and on the tracks.

The two studies that have not found reliable noise effects on reading may have poor statistical power. Both Cohen et al. (1980; 1986) and Moch-Sibony (1984) tested children from different schools, with different teachers, and in the former case from different school districts. In addition, both restricted their analyses to children from lower grades and did not attempt to tease out the

effects of noise on children of differing ability.

As indicated in several of the citations in Table 7, children in higher grades appear to be more negatively affected by noise exposure on reading than their younger counterparts (cf., Cohen et al., 1973; Green et al., 1982; Lukas et al., 1981; Maser et al., 1978). Children who have lower aptitude or other difficulties may be more vulnerable to the harmful effects of noise on reading (Maser et al., 1978). We also noted earlier several distraction studies indicating more disruptive effects on children with various learning deficiencies. Finally, Lukas and colleagues (1981) uncovered a significant synergistic effect of home and school noise exposure on reading scores.

Summary

Acute noise exposure appears to have little effect on reading and other intellectual activities. During early development, however, residential noise appears to delay cognitive development. In addition, chronic exposure to noise has been associated with reading deficits in seven out of nine studies, particularly for children in higher elementary school grades. There is also evidence that children with lower aptitude and those who also live in noisier homes appear more susceptible to the association of chronic noise exposure at school with reading deficits. The latter trend is interesting to consider in light of attentional data also showing more negative effects of noise exposure on children with pre-existing cognitive deficits.

DISCUSSION

Overview

We know with a good deal of certainty that chronic exposure to noise is associated in children with modest elevations of resting blood pressure, attentional deficiencies, and deficits in reading. Other effects suspected from chronic noise exposure include diminished task motivation, deficits in auditory discrimination, shifts in resistance to auditory distractors, poorer memory when high information processing demands are present, and deficits in infant cognitive development. The latter group of suspected effects include inconsistent data in some cases (auditory discrimination, resistance to distraction) or trends that have only been uncovered in one or two studies (motivation, memory, infant cognitive development). Tables 1-7 provide summary information that forms the bases for these conclusions.

Two major methodological shortcomings are prominent in the literature we have reviewed. Most critically, there is a total lack of prospective, longitudinal designs in this research area. Prospective, longitudinal studies are the strongest, *quasi*-experimental designs that can be applied in field studies and help deal with the host of threats (e.g., self-selection, confounding third variables) that plague correlational designs (see Cohen et al., 1986; Evans & Lepore, in press, for further discussion of methodological problems in field studies of environmental stressors). Such prospective studies must include well matched comparison groups and collect important personal data known to relate to outcomes of interest. Besides their utility as potential control variables in nonexperimental study designs, background variables can enhance statistical power by reducing unexplained variance in the outcome measure of interest. Studies on cardiovascular outcomes, for example, need to collect data on family history of hypertension. Research on reading should collect information on parental education levels and child's intelligence. Prospective, longitudinal designs will have to contend, however, with the potential interfering effects of selective attrition. As documented earlier, Cohen and his colleagues (1981), in one of only two longitudinal studies of noise and children, found that a year later children with the highest levels of blood pressure in their initial

cross-sectional analysis of quiet and noisy schools had moved out of the area. No such selective attrition was found among children in quiet schools.

The second major methodological shortcoming in nonauditory noise research and children has been lack of precision in two aspects of procedural conditions during testing. Testing conditions must be uniform and quiet. Reliance on archival measures of reading, for example, confounds acute with chronic noise exposure since ambient noise sources are likely to be present during the conduct of achievement tests. Testing must occur under quiet conditions in order to determine whether chronic noise affects reading or some other outcome of interest. More thorough audiometric screening is needed in nonauditory studies of noise and children to insure that the effects are not due to hearing loss.

Ecological Perspective

The purpose of this section is to outline some major conceptual shortcomings in the existing work on the nonauditory effects of noise on children and to lay out a preliminary research agenda. An ecological perspective (Bronfenbrenner, 1979) would significantly advance our understanding of this topic. Such a perspective includes greater attention to temporal issues plus the social and environmental contexts in which chronic noise exposure occurs. It also entails examination of the underlying, mediational processes that may link some of the psychophysiological, motivational, and cognitive processes related to chronic noise exposure.

Temporal parameters

Foremost, there has been a severe lack of developmental analyses, except in a few reading studies and in some of Wach's work on infant development in the home environment (see Table 7), of the effects of chronic noise on children. Developmental research approaches are critical in noise studies because it is highly likely that noise has differential impacts on physiological, cognitive and motivational processes as a function of developmental status. Consider for example reading acquisition. It is well established that reading acquisition depends upon the development of certain language competencies (e.g., phonological awareness) that are age

dependent (Mann & Brady, 1988). Noise exposure prior to or following the development of phonological awareness may not affect reading acquisition in the same way as noise exposure during the critical period of phonological awareness learning. Unless a developmental approach is added to noise research, such questions cannot be addressed.

A related but distinct conceptual limitation has been neglect of temporal parameters such as age at time of exposure and history of exposure to noise. For example, several studies on resistance to distractors from noise indicate the effects are contingent upon noise exposure history (see Table 5). Children exposed to ambient noise levels for shorter periods of time appear to be more resistant to the distracting properties of noise (see Table 5). These findings could relate to work on motivational deficiencies from prolonged noise exposure. Perhaps children attempt to filter out noise during early periods of exposure but eventually give up on this strategy. Duration effects could also relate to the specificity of resistance to auditory distractors. It would be interesting, for example, to investigate children's ability to filter out aircraft noise versus white noise or irrelevant speech, as a function of length and type of chronic noise exposure.

Unfortunately, we cannot disentangle age effects from exposure duration effects. For example, the apparently stronger linkages between chronic noise exposure and reading scores among older children (see Table 7) could be a function of a critical period of exposure or the result of longer, cumulative adverse impacts. Related to this latter option, we know nothing at this stage about the long-term effects of early childhood exposure to noise. What happens in later childhood or adolescence to children who spend all or part of their early years attending school or living near an airport or busy street?

Context

Greater attention to the ecological context in which chronic noise exposure occurs may prove fruitful for future research on noise and children. This ecological context might include more ecologically valid noise exposure estimates, attention to the indirect effects of noise on children via adult caregivers, and measurement of other social and environmental conditions co-varying with chronic noise exposure. With one

exception (Lukas et al., 1981) none of the field studies of noise and children have attempted to calculate overall noise exposure. It may be recalled that Lukas and colleagues found a synergistic effect of home and school noise exposure on reading.

Furthermore, the noise estimates that researchers have relied upon do not take into account children's mobility, exposure to noise sources in the home, or the attenuation properties of the structures they inhabit.

Nearly all of the work on noise and children involves comparisons between noisy and quiet settings. With one exception, Green et al. (1982), there is no information on dose response functions. Besides its evidentiary value, dose response curves would have public policy importance. We currently are unable to provide clear statements about what level of noise is harmful for children or to say what the efficacy would be of providing specific sound attenuation interventions.

Not only are children attending school or residing in homes in noisy areas exposed to noise but so are their principal caregivers. The behaviors of caregivers in noisy settings could indirectly influence children's responses to noise (Bronfenbrenner, 1979). For example, perhaps parents in noisy homes do not speak to their children or read to them as often as parents in quieter neighborhoods. Classroom observations and teachers' self-reports indicate that aircraft or train noises interrupt teacher lecturing (Crook & Langdon, 1974; Kyzar, 1977; Moch-Sibony, 1974), in one study causing a 10% reduction in total teaching time (Bronzaft & McCarthy, 1975). It is also well documented that teachers in noise-exposed classrooms report greater annoyance and fatigue during the school day in comparison to teachers from quiet classrooms (Crook & Langdon, 1974; Ko, 1979; 1981; Sargent et al., 1980). Therefore some of the adverse effects of noise on child development could be mediated through the negative impacts of noise on the child's primary caregivers. Parents and teachers may have less patience and energy to devote to children because of the adverse effects of noise on themselves. More directly, noise may alter the manner in which parents and teachers instruct children, altering reading or speaking patterns. Recent data indicate that parent-child interactions may be affected by household noise levels. Parents from noisier homes appeared less

interested in their children's activities and talked less with their children (Wachs, 1989; Wachs & Camli, 1991). Controls for education levels of the mother did not change these findings.

Ambient noise exposure rarely occurs in isolation of other social and environmental problems. Noisy environments frequently covary with crowding and pollution and are often part of the fabric of poverty, including substandard housing, conflictual households and various other psychosocial strains. Although the ecological covariation of noise with other adverse environmental and social factors makes it difficult to isolate the effects of noise on children, we should be mindful that the harmful effects of noise may be amplified by the context in which noise is often embedded. It may be precisely those children who develop under such impoverished physical and social circumstances who are most vulnerable to the harmful effects of noise (Bronfenbrenner, 1979; Evans et al., 1990). We have recently found among adults, for example, that the negative effects of residential crowding on psychological distress are significantly worsened by chronic strains associated with poverty (e.g., insufficient utilities, poor housing quality, financial insecurities) (Lepore et al., 1991).

Noise levels may also operate within a context of important individual differences among children. There is some evidence that some children are more at risk for adverse noise effects on cognitive development. Less intelligent children's math and reading performance appears more sensitive to noise exposure (Johansson, 1983; Maser et al., 1978). Studies of young children and infants suggest greater susceptibility to chronic noise-related problems among boys in comparison to girls (Wachs, 1978; 1987; 1989). On the other hand, girls may be more distracted by acute noise exposure (Christie & Glickman, 1980; Hambrick-Dixon, 1988). Cognitive performance during acute noise appears to be disrupted more by noise for individuals with pre-existing learning deficits (cerebral palsy, learning disabled).

In addition to alerting researchers and policy makers to the potential of subgroups of children at high risk for negative effects of noise, these findings also have another important implication. Some of the small or even conflicting nonauditory effects of noise reviewed herein may be conservative estimates of noise effects since they by and large have not examined interactive effects.

While in some cases there may be little if any overall noise effects on children, it would be erroneous to conclude from such data profiles that noise is an inconsequential environmental problem for children. There may be large segments of the child population whose development may be significantly compromised by noise exposure early in life.

Mediational processes

Another area of future research that might emanate from an ecological perspective on noise and children is greater scrutiny of the potential interplay among the various psychophysiological, cognitive, and motivational processes that appear to be affected by chronic noise exposure. Cohen and his colleagues (1973) examined Deutsch's (1964) hypothesis that children chronically exposed to noise may learn to tune out auditory stimuli indiscriminantly and thus not pay sufficient attention to speech. They found that children from noisier apartments were deficient in auditory discrimination. Of particular interest, this deficiency significantly accounted for the poorer reading abilities of the noise-exposed children. This study stands alone as the only analysis of an underlying process to explain how noise affects children.

Given the findings (see Table 4) that noise can mask speech and evidence that speech perception and other linguistic skills such as phoneme awareness are critical precursors to reading acquisition (Mann & Brady, 1988), more work is called for on the effects of chronic noise exposure on psycholinguistic processes and their potential mediating link with reading. Other pathways warranting further investigation include those between chronic noise exposure, motivation, attention, and reading.

There are also plausible interconnections among chronic noise exposure and several of the cognitive processes we have reviewed. For example, people chronically exposed to noise may become more resistant to the distracting effects of acute noise exposure during a task because they can ignore or filter out auditory distractors. This ability may occur as a result of learning to tune out or filter auditory sounds. Thus one would expect a relation between the ability to ignore auditory distractors and deficits in auditory discrimination associated with chronic noise exposure. Analogously, we would expect a mediational pathway

between chronic noise exposure, attentional focusing and deficits in incidental memory performance.

Thus rather than only treating different outcome variables such as reading, attentional processes, and resistance to distraction as separate correlates or effects of noise exposure, more thought and careful analyses are required to investigate how these variables may form causal links to one another. In other words, both the direct and indirect pathways of the nonauditory effects of noise on children need to be investigated. From a theoretical and public policy perspective, this is perhaps most crucial in the case of reading. Although stronger data on the adverse effects of chronic noise exposure on reading would be valuable from an evidentiary point of view, what is of paramount importance now is a shift in focus to explanations of why and how chronic noise adversely influences reading acquisition.

There may also be some potent interplay among psychophysiological processes and some of the cognitive strategies apparently influenced by chronic noise exposure. For example, presumably it takes some effort to tune out or ignore noise. Experimental data as well as field studies with adults indicate that cognitive efforts to maintain task performance during noise come at a price of heightened sympathetic arousal (Tafalla & Evans, 1993; Welch, 1979). When performance suffers under noise, slight or no sympathetic arousal is apparent. However, if performance is maintained under noise which is possible except under tasks of very high load demands on attention and working memory (Cohen et al., 1986; Smith, in press), then indices of sympathetic arousal should be substantially elevated during noise exposure.

The associations between chronic noise exposure in children (see Table 1) and heightened blood pressure raise several important questions about mechanisms. For example, are blood pressure elevations caused by repeated sympathetic arousal induced by the distracting and interfering properties of community noise conditions? Alternatively, are the elevations mediated by adrenocortical activity and thus primarily indicative of chronic stress? To our knowledge, no analyses of various psychoneuroendocrine pathways between noise and blood pressure elevations have been investigated. Given the central role of cognitive appraisal in psychological

stress, it would also behoove researchers to examine whether psychosocial factors such as perceived control, self-confidence to ignore/tune out noise, or annoyance, moderate the effects of noise on blood pressure and other psychophysiological processes among children.

Another fruitful area of psychophysiological research would be to investigate the potential role of chronic noise exposure in cardiovascular reactivity. Individual differences in reactivity to standard psychosocial elicitors of stress (e.g., mental arithmetic) may be predictive of cardiovascular disease (Krantz & Manuck, 1984; Matthews et al., 1986). Research on cardiovascular reactivity in both adults and children has ignored the potential etiological role of chronic exposure to environmental stressors. More detailed analyses, focusing on possible behavioral toxicological effects of in utero or neonatal noise impacts are also called for. This is especially pertinent in light of contemporary medical practices such as ultrasound monitoring or placement of premature infants in neonatal intensive care units.

Large numbers of children both in America and, in rapidly growing numbers in the Third World, are being exposed to levels of ambient noise that are not only a threat to hearing but may have harmful effects on physiological and cognitive development. The potential for harmful effects from chronic noise exposure on children's development is great; what we know with certainty about the problem is, unfortunately at the moment, insufficient. At the same time, there is a foundation of evidence clearly suggesting potentially harmful effects from chronic noise exposure among children. We also have enough data on hand to formulate preliminary models of underlying, mediating mechanisms that could account for the effects of noise. It is also clear that more longitudinal work with prospective designs is crucial to definitively demonstrate the relationships between chronic noise exposure and children's development. Such designs afford stronger internal validity given the impossibility of randomly assigning children to varying community noise levels. Longitudinal designs allow us to examine changes in behaviors over time plus provide the opportunity to examine whether self-selection has occurred prior to noise exposure.

ENDNOTE

This article is based in part on earlier presentations at the Fifth International Congress on Noise as a Public Health Problem, Stockholm, Sweden and A Strategy for Noise Prevention in the 90's, American Speech and Hearing Association, Washington, DC. Preparation of this article was partially supported by the National Heart Lung and Blood Institute, RO1 HL47325-01A1, the Nordic Noise Council, and the Swedish Environmental Protection Board.

CHRONIC NOISE AND PSYCHOLOGICAL STRESS

Gary W. Evans,¹ Staffan Hygge,² and Monika Bullinger³

¹Cornell University; ²Royal Institute of Technology, Gävle, Sweden; and ³University of Munich

Abstract—This article illustrates the value of incorporating psychological principles into the environmental sciences. Psychophysiological, cognitive, motivational, and affective indices of stress were monitored among elementary school children chronically exposed to aircraft noise. We demonstrate for the first time that chronic noise exposure is associated with elevated neuroendocrine and cardiovascular measures, muted cardiovascular reactivity to a task presented under acute noise, deficits in a standardized reading test administered under quiet conditions, poorer long-term memory, and diminished quality of life on a standardized index. Children in high-noise areas also showed evidence of poor persistence on challenging tasks and habituation to auditory distraction on a signal-to-noise task. They reported considerable annoyance with community noise levels, as measured utilizing a calibration procedure that adjusts for individual differences in rating criteria for annoyance judgments.

Since the early 1970s, psychologists have contributed insights to the analysis of environmental problems (Ittelson, 1976). Current concerns focus on human perceptions of environmental risks (Vaughan, 1993; Wandersman & Hallman, 1993) and the role of the physical environment in human health and well-being (Baum & Fleming, 1993). The concept of psychological stress has proven a useful heuristic to conceptualize human responses to suboptimal environmental conditions (Cohen, Evans, Stokols, & Krantz, 1986; Evans & Cohen, 1987). The present article provides evidence that chronic noise exposure is associated with psychophysiological, cognitive, motivational, and affective indices of psychological stress.

Laboratory studies have shown that acute noise degrades complex task performance (Smith & Jones, 1992) and elevates neuroendocrine and cardiovascular markers of psychological stress (Evans & Cohen, 1987). Chronic noise is associated with elevated cardiovascular functioning among children (Cohen et al., 1986) and is consistently correlated with reading deficits among elementary school children (Evans & Lepore, 1993). Experimental exposure to uncontrollable noise produces learned helplessness (Glass & Singer, 1972; Seligman, 1975), and long-term exposure to community noise may contribute to helplessness among children (Cohen et al., 1986).

The present study extends these earlier findings in several respects. This is the only study to examine neuroendocrine indices of chronic stress among persons exposed to community noise. Without neuroendocrine markers, it is difficult to interpret children's elevated cardiovascular reactions to chronic noise exposure as evidence of stress (Grunberg & Singer, 1990;

Krantz & Falconer, 1995). Furthermore, although resting cardiovascular levels are an important indicator of health, cardiovascular reactivity to acute stressors may contribute more to the etiology of coronary heart disease (Krantz & Manuck, 1984).

Several measures of human performance were also assessed in the present study. Speech perception was examined because of its relevance to noise and its potential role in reading acquisition (Mann & Brady, 1988). We also examined two attention tasks, choice reaction time and visual search. There is some evidence of deficits in both working memory (Hamilton, Hockey, & Rejman, 1977) and long-term memory (Hygge, 1993) during acute noise exposure. No research has examined the generalizability of these types of findings to persons chronically exposed to noise.

Many prior studies have uncovered associations between ambient noise levels and reading deficits (Evans & Lepore, 1993). Unfortunately, all of these studies have relied on archival reading achievement scores, thereby confounding chronic and acute noise exposure. We administered a standardized reading test under carefully controlled, quiet conditions.

Children chronically exposed to noise (Cohen et al., 1986) and to crowding (Rodin, 1977) suffer increased vulnerability to learned helplessness. We designed a conceptual replication of these earlier findings, adapting Glass and Singer's (1972) after-effects paradigm for use with children. Numerous acute stressors reliably decrease persistence on challenging puzzles presented immediately after stressor exposure (Cohen, 1980; Glass & Singer, 1972). This paradigm, to our knowledge, has never been adapted for children or been used to examine chronic stress and motivation.

Although adults living in noise-impacted communities react with annoyance (Evans & Cohen, 1987), very little is known about children's affective responses to noise. We investigated this issue in two ways. First, we examined children's annoyance to a series of standardized auditory stimuli, as well as to community noise sources. This procedure enabled us to examine both raw and calibrated annoyance ratings. Calibration may enhance the sensitivity of annoyance scales given large individual differences in response criteria for assessing annoyance (Berglund & Nordin, 1990). The second way we investigated children's affective reactions to chronic noise exposure was by assessing quality-of-life ratings. Quality of life can be assessed accurately in young children (Bullinger, von Mackensen, & Kirchberger, 1994), indexing perceived physical, psychological, social, and daily functioning.

Summarizing, we employed the concept of psychological stress as a heuristic to conceptualize human responses to suboptimal environmental conditions. Our analyses focused on psychophysiological, cognitive, motivational, and affective processes in relationship to chronic noise exposure among young children.

METHOD

Subjects

Participants were 135 third and fourth graders (mean age = 10.78 years) living either in a high-noise-impact urban neighborhood (24-hr Leq = 68.1 dBA; peak = 79.8 dBA) surrounding the Munich International Airport or in a quiet urban neighborhood (24-hr Leq = 59.2 dBA; peak = 69.0 dBA) in Munich. An increase of 10 dBA is experienced as approximately twice as loud. Leq is an unweighted average of sound pressure intensity. Children in the quiet, comparison areas were matched to the children in the noise-impacted area according to socioeconomic status. Households did not differ in type of occupation, $\chi^2(4, N = 116) = 4.96$; parental education, $t(122) = 1.58$; or family size, $t(122) = 1.10$. All of the children in this study first passed an audiometric screening to ensure that none had hearing loss.

Dependent Measures

Psychophysiological

Blood pressure was measured with an automated blood pressure monitor (A&D Digital, UA 751) while the child was seated comfortably. Twelve-hour overnight urinary epinephrine and norepinephrine were assayed with high-performance liquid chromatography with electrochemical detection (Riggin & Kissinger, 1977), and cortisol was measured with a radioimmune assay; iodine¹²⁵ (Baxter Travenol Diagnostics, Cambridge, Mass.). Sample volumes were determined, and a small amount of urine was randomly extracted and frozen at -70°C . Half of the extracted urine was also pH adjusted to further inhibit oxidation of catecholamines. See Grunberg and Singer (1990) and Lundberg (1984) for more details on utilizing urinary neuroendocrine measures as indices of chronic stress.

Cognitive

Cognitive measures included indices of attention, memory, and reading.

Attention. A signal-to-noise measure assessed speech perception against a noise background. Each child listened to a story at his or her preferred volume. This volume level defined continuous background noise (road traffic, aircraft, or broadband) played throughout the story. At fixed, random intervals, the storyteller's voice dropped 10 dBA, and the child readjusted the story volume to a comfortable listening level.

An embedded figures task required the children to search for any one of five target figures contained within complex line drawings.

In a simple choice reaction time task, the children were presented with random sequences of red and green lights and were instructed to press the key labeled "red" or "green" to indicate the color of each light. Two 8-min sequences were run. The first session was conducted in silence and the second one in aircraft noise (80 dBA Leq).

Memory. Each child read an interesting text. Random, intermittent broadband noise bursts (peak dBA = 80) were pre-

sented throughout the 12-min period. A day later, the child's long-term recall for the text was assessed.

Working memory span was assessed by presenting consonants at the rate of one per second. At random intervals, the sequence was stopped and the child was requested to recall, in order, as many consonants as possible. Accuracy was defined as correct recall of the consonants in serial position (Hamilton et al., 1977).

Reading. Children read paragraphs as well as word lists on the Biglmaier (1969) Reading Test (a valid and reliable German standardized test) under quiet conditions. Standardized scoring criteria were applied to each subscale.

Motivation, annoyance, and quality of life

Motivation. After reading the long-term memory text under noisy conditions, the children were given two line-tracing puzzles adapted from Glass and Singer's (1972) aftereffects paradigm. The puzzles consisted of animal names connected together by lines. Children "traveled" to each animal via the connecting lines but without lifting their pencils or retracing any line. They attempted the first puzzle until they solved it or gave up, and then moved on to the second puzzle. The initial puzzle was insoluble, and the index of motivation was the number of attempts to solve this puzzle. The second puzzle was soluble. The order of the two puzzles was deliberately fixed so that each child would experience success following initial failure on the first puzzle. All children solved the second puzzle. The task lasted 10 min. Attributions for failure on the initial puzzle were also assessed. These data are not included here because of space limitations.

Annoyance. The children provided magnitude estimates of noise annoyance (0 = not at all annoying; 100 = the most noise one could withstand without putting one's hands over one's ears) by moving their fingers along a vertical graphic scale. They were trained how to use this scale by first jumping as far as possible, which was designated as 100. They then jumped distances equivalent to magnitudes of 50, 25, 75, and 10.

Four-s noise bursts were randomly presented over headphones at 42, 54, 66, 78, and 90 dBA Leq. Broadband noise, aircraft noise, and road traffic noise were presented in separate sets. The annoyance rating for each noise burst was indicated on the vertical graphic scale from 0 to 100. The children also indicated how annoyed they were with community noise levels. Both Bandura and Schunk's (1981) original scale development and our own pilot work indicate high reliability for this magnitude estimation procedure with young children.

Nine uncalibrated noise ratings were summed to provide the community noise rating for each child. Calibrated scores were individually adjusted by the slope of the regression line fitting each child's annoyance ratings of the broadband-noise standard stimuli to his or her community noise estimates. For more details on calibration scoring procedures, see Berglund and Nordin (1990).

Quality of life. Quality of life was assessed by the KINDL, a valid and reliable index of the four principal domains of qual-

ity of life (physical, psychological, social, functional daily life; Bullinger et al., 1994).

Procedure

Testing occurred in a climate-controlled, sound-attenuated trailer at the children's school. Forty-eight-hr outdoor noise levels were monitored at the trailer 6 m above ground with a B&K Model 4426 Sound Meter.

Experimental tasks were conducted in fixed order on 2 consecutive days. Children were run individually in booths, with an experimenter sitting across a small table from each child. On Day 1, each child was first taught the magnitude estimation procedure (jumping), as described. Then an initial blood pressure reading was taken, and the child completed a brief mood scale. Then the following tasks occurred: noise annoyance; audiogram; blood pressure; mood scale; signal-to-noise measure; blood pressure; long-term memory text with noise, accompanied by blood pressure readings every 4 min; Glass and Singer aftereffects measure (line-tracing puzzles); and blood pressure. Total testing time for Day 1 was 85 min.

At the end of Day 1, parents were given a urine specimen bottle and instructions for collecting the 12-hr overnight sample. Parents were requested to collect in the container all urine the child voided that same night and the next morning between 20:00 and 8:00. This container was kept refrigerated and contained a preservative.

On Day 2, parents brought back the urine specimen container. Testing began with an initial blood pressure reading, followed by a mood scale and then a brief interview, a blood pressure reading, recall of the prose text from the day before, the standardized German reading test, a blood pressure reading, the embedded figures task, the test of working memory, another blood pressure reading, and finally the reaction time task, accompanied by blood pressure readings every 4 min. The child was then given a gift and provided the opportunity to ask questions about the study. Total time for Day 2 was 87 min.

The KINDL was administered at home prior to the laboratory testing.

RESULTS

Psychophysiological

Neuroendocrine

Overnight resting levels of urinary catecholamines were significantly different between the children chronically exposed to

aircraft noise and those unexposed: $t(120) = 2.89, p < .025$, for epinephrine and $t(120) = 3.43, p < .001$, for norepinephrine. (All statistical tests are two-tailed unless otherwise indicated.) As shown in Table 1, resting, baseline adrenomedullary neuroendocrine levels were elevated in association with chronic exposure to high levels of community noise. There was, however, no significant relationship between chronic exposure to aircraft noise and cortisol levels, $t(120) < 1.0$.

Baseline cardiovascular

There was a marginally significant relationship between noise exposure and baseline systolic blood pressure, $F(1, 109) = 3.03, p < .08$. (Degrees of freedom vary throughout because of missing data and in the case of blood pressure readings, because some readings were clearly incorrect.) Baseline diastolic blood pressure was unrelated to noise exposure, $F(1, 109) < 1.0$. Baseline measures were calculated by taking the average of three resting indices from Day 1 and three resting measures from Day 2. On each day, an initial resting blood pressure reading was taken to help desensitize children to the procedure. This initial reading is not included in the results reported here. The blood pressure analyses include a covariate (ponderosity) for body fat.

Cardiovascular reactivity

There was significantly lower reactivity in systolic blood pressure among children chronically exposed to aircraft noise in comparison to their quiet-community counterparts, $F(1, 109) = 15.62, p < .001$ (see Table 1). Diastolic reactivity was unrelated to chronic noise conditions, $F(1, 109) < 1.0$. Cardiovascular reactivity was calculated by subtracting the resting baseline index from the initial blood pressure reading during the prose reading for the long-term memory task.

Cognitive

Attention

As shown in Table 2, children from noisy communities chose a lower signal-to-noise ratio than did those from quiet communities, $t(103) = 1.78, p < .05$ (one-tailed). The type of background noise (road, aircraft, broadband) did not interact with the main effect of community noise level. Noisy children's habituation to auditory distractors generalized across different types of noise. Preferred volume level for the signal (story reading) under quiet conditions was equivalent between the two groups, $t(103) < 1.0$. The two noise groups did not differ in

Table 1. *Psychophysiological measures*

Variable	Quiet communities	Noisy communities
Epinephrine	368.62 ng/hr	526.36 ng/hr
Norepinephrine	766.22 ng/hr	1,108.82 ng/hr
Cortisol	3.62 µg/hr	3.75 µg/hr
Resting diastolic blood pressure	63.56 mm Hg	63.39 mm Hg
Resting systolic blood pressure	100.73 mm Hg	102.65 mm Hg
Reactivity diastolic blood pressure	-0.71 mm Hg	-0.34 mm Hg
Reactivity systolic blood pressure	1.66 mm Hg	-3.31 mm Hg

Chronic Noise and Psychological Stress

Table 2. Cognitive measures

Variable	Quiet communities	Noisy communities
Signal/noise	10.87 dB	6.81 dB
Embedded figure (number correct: 0-12)	5.60	6.10
Reaction time (quiet conditions)	440.7 ms	450.0 ms
Reaction time (noisy conditions)	438.0 ms	454.0 ms
Long-term recall (number correct: 0-25)	5.76	4.54
Reading (number of errors)		
Text	41.30	50.80
Word recognition	4.57	7.10

performance on the embedded figures task, $t(131) < 1.0$, nor in reaction times either under quiet ($t(108) < 1.0$) or under noisy ($t(108) < 1.0$) testing conditions.

Memory

On the long-term recall task, children from noisy communities performed worse than their counterparts, $t(130) = 2.13$, $p < .05$. There were slight reductions in working memory span among children chronically exposed to noise. Only one of these differences was statistically significant (the fifth serial position from the last item presented).

Reading

As shown in Table 2, children from noisy communities had significantly more errors on the text subscale of the German standardized reading test than children from quiet communities, $t(127) = 2.02$, $p < .05$. On the word list subscale, children from the noisy and quiet areas differed on the most difficult section of the test, $t(125) = 2.10$, $p < .05$. The two groups did not differ on the easy and intermediate portions of the test. Children from the two groups completed equivalent portions of both the prose and the word list tests.

Motivation, Annoyance, and Quality of Life

Motivation

Children from noisy communities persisted less than children from quiet communities on the insoluble puzzle in the aftereffects task, $t(130) = 2.35$, $p < .02$ (see Table 3).

Annoyance

Children living in noisier areas were significantly more annoyed by the noise in their communities, as indexed by calibrated community measures, $t(132) = 2.17$, $p < .05$. The raw, uncalibrated scores showed the same trend.

Quality of life

As can be seen in Table 3, trends on the KINDL index were generally in the expected direction, but only the difference on the psychological subscale proved statistically significant, $t(124) = 2.47$, $p < .01$.

DISCUSSION

This article demonstrates the value of integrating psychological principles into the environmental sciences. Psychophysiological stress processes linked to coronary heart disease; central cognitive processes, including speech perception, memory, and basic reading skills; motivation; and emotional affect are all associated with chronic exposure to noise among children.

Our data reveal a link between chronic exposure to noise in the community and elevated neuroendocrine markers of stress, along with marginally increased resting levels of systolic blood pressure. Similar small increments in blood pressure have been noted previously (Cohen et al., 1986), but these are the first data on neuroendocrine markers of chronic noise exposure. We also reveal differential cardiovascular reactivity in response to task demands as a function of chronic environmental stress. Our pattern of psychophysiological stress findings (elevated baseline indices, diminished reactivity to challenge) is potentially quite important to consider in light of theories about stress and disease. Chronic stressor exposure, particularly exposure to stressors unamenable to instrumental control, may deplete coping capacity, rendering the organism less able to mobilize resources when needed to respond to acute challenges (Lepore & Evans, in press). At the same time, chronically elevated baseline indices of neuroendocrine and cardiovascular functioning

Table 3. Motivation, annoyance, and quality-of-life measures

Variable	Quiet communities	Noisy communities
Motivation (number of attempts to solve insoluble puzzle)	6.77	5.48
Calibrated annoyance (broadband noise equivalents)	62.49	67.47
Quality of life ^a		
Psychological (11-55)	30.20	27.85
Physical (9-45)	26.88	26.91
Social (9-45)	26.42	26.06
Functional (11-55)	30.04	29.33

^aThe higher the score, the higher the quality of life.

can cause physical damage directly via changes in hemodynamics and arterial tissue structure and indirectly via suppressed immune functioning (Cohen, Kessler, & Gordon, 1995).

Several cognitive processes are associated with community noise levels. Prior studies have shown correlations between ambient noise exposure and reading levels (Evans & Lepore, 1993). We demonstrated this association with a standardized reading test administered under quiet, controlled conditions. All prior studies have utilized archival reading records of tests administered under ambient testing conditions in school and thus have confounded chronic levels of noise exposure with acute levels during the testing periods. An important policy question raised by our data is, once children fall behind in reading skills because of noise exposure, do these deficits persist, or continue to widen, with continued noise exposure? We also do not know whether noise-related reading deficits are reversible should children change their residence or if extensive sound attenuation is installed in buildings where the children spend most of their time (i.e., school, home).

The cognitive data reveal a mixed pattern of results. Long-term memory was worse among the schoolchildren from noisy communities. Asked to recall information from an interesting text they had read the day before, they performed less accurately than children from quiet communities. Similar trends have been shown in laboratory research on acute noise (Hygge, 1993). Chronic noise exposure may diminish working memory span, although the effects appear quite small.

Neither the embedded figures task nor the reaction time task revealed any associations with noise exposure. Both of these results replicate studies of acute noise (Broadbent, 1979; Smith & Jones, 1992).

Children chronically exposed to noise were less sensitive to distracting, background noise during a speech perception task than were children from quiet neighborhoods. The noise-exposed children consistently chose a lower signal-to-noise ratio when readjusting a speaker's voice against noisy background conditions. Moreover, this perceptual adaptation generalized across different noise sources. Broadband noise, road traffic noise, and aircraft noise all revealed the same pattern. Under quiet conditions, preference for volume level of the speaker's voice was the same for children from quiet and noisy neighborhoods. These perceptual adaptation findings are consistent with prior work suggesting that children cope with chronic noise exposure by tuning out auditory stimuli (Cohen et al., 1986).

Overall, the cognitive data add to the growing list of studies indicating selective impairments in cognitive functioning among children reared under poor environmental conditions. In young children, more complex, higher order skills, such as reading, problem solving, and comprehension of difficult materials, appear vulnerable to adverse environmental conditions (Cohen et al., 1986; Evans & Cohen, 1987; Wachs & Gruen, 1982). The perceptual adaptation findings also raise important questions about the long-term consequences of children's coping mechanisms. Children may cope with adverse environmental conditions by developing cognitive strategies (e.g., tuning out ambient noise) that have consequences for language acquisition and speech processing.

We adapted Glass and Singer's (1972) stressor aftereffect

paradigm to measure potential motivational impacts of chronic stressor exposure on the children. Children from noisy communities exhibited less persistence in task performance when challenged. These data conceptually replicate earlier findings utilizing a different paradigm to assess motivational deficiencies in children chronically exposed to crowding (Rodin, 1977) and to noise (Cohen et al., 1986). The potential role of adverse physical or psychosocial conditions in early motivational development is an important and largely neglected topic of psychological inquiry.

Children living in noisy communities find the levels of environmental noise where they live annoying. Both raw and calibrated, the magnitude estimations of annoyance indicate this trend. These children also rated the quality of life, particularly psychological, in their communities as poorer than did the children from quiet communities.

Although we demonstrated that the noisy and quiet communities were similar with respect to socioeconomic status, the correlational design of our study precludes causal conclusions. Nonetheless, our preliminary evidence warrants more intensive follow-up, utilizing prospective, longitudinal field studies of chronic environmental stressors and children's health and well-being.

To summarize, our results reflect a general pattern of adverse psychological stress reactions associated with chronic exposure to noise among elementary-school-aged children. The children who were studied showed no apparent auditory damage during standard audiometric examination. Both neuroendocrinological and cardiovascular indices of chronic stress were elevated; long-term memory, speech perception, and standardized reading test scores indicate deficits; and children living proximate to a major airport reported more annoyance and a lower quality of life than did children in quiet communities. These data are sobering when one considers that more than 10 million American schoolchildren are exposed to comparable noise levels and that worldwide population exposure to noise is escalating exponentially with accompanying industrial development (Suter, 1991). Psychological principles have much to offer to the conceptualization and analysis of environmental problems.

Acknowledgments—We are extremely grateful to the families who cooperated with this research project. We thank Sylvia von Mackensen, Gerhard Helm, Gunnar Söderqvist, and Christian Wigren for their dedication to this project. Financial support for this research came from the Society for the Psychological Study of Social Issues, the National Institutes of Health (ROI HL 4732 01A), the Nordic Noise Group, the Nordic Scientific Group for Noise Effects, the Swedish Environmental Protection Agency, and the German Research Foundation. The third author was also supported by the DFG Heisenberg Fellowship.

Aftereffects of Stress on Human Performance and Social Behavior: A Review of Research and Theory

Sheldon Cohen
University of Oregon

A review of experimental and correlational studies of the aftereffects of stress on performance suggests that these effects occur as a consequence of a wide range of unpredictable, uncontrollable stressors including noise, electric shock, bureaucratic stress, arbitrary discrimination, density, and cold pressor. Moreover, these effects are not limited to a restricted range of stressful situations that involve a lack of predictability and controllability over a distracting stimulus, but they can also be induced by increased task demand. Interventions that increase personal control and/or stressor predictability are effective in reducing poststressor effects. There is also evidence for poststimulation effects on social behavior that generally involve an insensitivity toward others following stressor exposure. Studies of exposure to environmental stressors in naturalistic settings report effects similar to those found in laboratory settings. Several theories (e.g., psychic cost, learned helplessness, arousal) are examined in light of existing evidence. Although some theories receive more support than others, it is suggested that the reliability and the generality of poststimulation effects occur in part because of a multiplicity of causes.

The notion that continued exposure to a stressor may produce effects that appear only after stimulation is terminated has been central to the stress literature for a number of years. This assertion is derived principally from an adaptive-cost hypothesis which suggests that although humans can often adapt to extreme conditions, there are cumulative costs of adaptation. An early form of this hypothesis, which emphasized the biological costs of the adaptive process, was proposed by Selye (1956). He asserted that after prolonged exposure to a stressor, one's adaptive reserves are drained, resistance breaks down, and exhaustion sets in. Others (Basowitz,

Persky, Korchin, & Grinker, 1955; Dubos, 1965; Milgram, 1970; Wohlwill, 1966) make similar points in regard to poststressor effects on behavior. In the words of Dubos, "Although man is highly adaptable and can therefore achieve adjustments to extremely undesirable conditions, such adjustments often have . . . indirect effects that are deleterious" (1968, p. 139).

The early empirical work on the aftereffects of stress focused on stressor effects on physical and psychological health. For example, there are a number of studies on the cumulative effects of disease, malnutrition, and toxic chemicals on normal bodily functions (see Dubos, 1965). There is also an extensive research literature on the association between subjects' reports of recent life changes and subsequent changes in somatic and psychological health (cf. Dohrenwend & Dohrenwend, 1974).

It was only recently, however, that the first experimental studies of the postexposure effects of stressors on behavior were reported (Glass & Singer, 1972). The major emphasis

Preparation of this article was supported by National Science Foundation Grant BNS 77-08576 and by National Institute of Environmental Health Sciences Grant 1 R01 ES01764-01.

The author is indebted to Gary Evans, David Krantz, and Myron Rothbart for comments on an earlier draft.

of Glass and Singer's research program was on determining whether the cognitive context of a stressor mediated performance on tasks administered immediately after stressor termination. Based on earlier research which demonstrated that the ability (or perceived ability) to predict or escape an aversive event reduced both the aversive quality of the stimulus (e.g., Corah & Boffa, 1970; Pervin, 1963) and the resultant physiological response (e.g., Champion, 1950; Corah & Boffa, 1970; Stotland & Blumenthal, 1964), they hypothesized that performance following stress exposure may be similarly mediated by stressor predictability and perceived control over stressor termination.

Glass and Singer's (1972) early work was strongly influenced by the adaptive-cost hypothesis. Specifically, they suggested that deleterious effects on performance following exposure to unpredictable, uncontrollable stressors should occur because the substantial effort required to adapt to these aversive events would leave one less able to cope with subsequent demands and frustrations. Since predictable and controllable stressors were viewed as considerably less aversive, adaptation to these stressors would presumably require less effort and therefore would be less likely to impair poststimulation performance. At the completion of their research program, Glass and Singer concluded that exposure to unpredictable, uncontrollable stressors produces poststimulation deficits in performance on a number of tasks and that the ability to predict and/or control the stressor ameliorates these effects. However, they also concluded that the adaptive process is not responsible for these poststress performance deficits.

Since the publication of the Glass and Singer (1972) book there have been over 30 published studies on the poststimulation effects of stressors on performance and social behavior. Moreover, a number of cognitive and motivational explanations for the after-effects of stress have been offered and in some cases tested. This article reviews the existing laboratory and field research on the after-effects of stress on performance and interpersonal behavior and outlines a number of possible explanations for these effects. The re-

search review is divided into five major sections. The first section examines studies that have attempted to determine whether there are effects of unpredictable, uncontrollable stress on performance following stressor termination. The second and third sections examine those studies that attempt to ameliorate poststimulation effects by providing subjects with a predictable version of the stressor and/or with control over the stressor. The fourth section describes studies of the poststimulation effects of stress on social behavior, and the fifth section reviews naturalistic studies of stress aftereffects. Finally, the theory review examines each of eight alternative explanations for poststress effects on performance and social behavior in light of existing data and reevaluates the adaptive-cost hypothesis.

Research Review

Aftereffects of Unpredictable and Uncontrollable Stressors

Studies reviewed in this section compare performance after exposure to an unpredictable, uncontrollable stressor with performance in an experimental control condition in which there was either a less intense form of the stressor or no stressor exposure. A number of these studies also included conditions in which the stressor was predictable and/or controllable. These conditions are not discussed here but are presented in later sections.

Noise. Glass and Singer (1972) reported five studies that examined poststimulation effects after exposure to unpredictable, uncontrollable noise (pp. 47, 50, 52, 55, 80). Their studies typically involved approximately 25 minutes of exposure to 108-110-dB (A) random-intermittent bursts of a broadband conglomerate noise made up of a number of fairly typical urban sounds. During noise exposure, the subject worked on simple cognitive tasks. Autonomic response was monitored during stressor exposure. Immediately after the noise exposure period, one or more of three measures were administered to the subject: the Feather (1961) tolerance for frustration task (studies reported in Glass & Singer, 1972, pp. 47, 52, 55), a proofreading

task (Glass & Singer, 1972, pp. 47, 50, 52, 55, 80), and the Stroop (1935) Color-Word task (Glass & Singer, 1972, p. 80).

The Feather measure requires a subject to work on two soluble and two insoluble line puzzles for 15 minutes. The subject can only work on one puzzle at a time and cannot return to a puzzle after moving on to the next. The puzzles are presented so that the first and third are insoluble and the second and fourth are soluble. The criterion measure (amount of tolerance for frustration) is the number of trials—puzzle cards—or amount of time spent on insoluble puzzles. The proofreading task involves correcting misspellings, grammatical mistakes, incorrect punctuation, transpositions, and typographical errors. Each subject is usually given between 8 and 15 minutes (although nothing is said about time), and the quality of performance is measured as the percentage of errors not found of the total number of errors that could have been detected at the point the subject was told to stop. In the Stroop task, task stimuli are the names of four colors (green, red, orange, and blue), each of which is printed in one of the other three colors. For example, the word *green* may be printed in red, orange, or blue. The four color words are presented randomly over a series of trials, and the subject is asked to name the color in which the word is printed. A control version of the task, in which subjects are required to name the colors of sets of asterisks or zeros, is also administered to each subject. Stroop interference scores (on accuracy and speed) are obtained by subtracting a subject's score on the control stimuli from the subject's Stroop score.

Poststimulation deficits in performance occurred in all five of the studies and on all three of the tasks. Except for a lack of effect on the proofreading task in one study (p. 80), the effects were totally reliable. Moreover, Glass and Singer (1972, p. 47; see also, Glass, Singer, & Friedman, 1969, Experiment 1) reported poststimulation effects following exposure to 56-dB random noise as well as to the more intense 108-dB bursts.

There have been a number of successful attempts at replicating the poststimulation ef-

fects of unpredictable high-intensity noise on human performance. Thus Rotton, Olszewski, Charleton, and Soler (1978) reported less tolerance for frustration among subjects exposed to 80-dB (A) random-intermittent bursts of conglomerate noise than among subjects working in quiet. Likewise, Gardner (1978) found that subjects exposed to random-intermittent bursts of conglomerate noise at 100 dB (A) provided poorer poststimulation performance on a proofreading task than did subjects not exposed to noise. Percival and Loeb (in press, Experiment 1) found less tolerance for frustration among subjects exposed to random-intermittent, 95-dB (A), conglomerate noise than among subjects exposed to a continuous, soft (46-dB) broadband sound. Percival and Loeb did not, however, find poststimulation effects on proofreading performance.

Studies of the impact of variable continuous noise, when there are unpredictable components of the noise (e.g., aperiodic bursts of static or office noise), also report poststimulation effects. Thus Wohlwill, Nasar, DeJoy, and Foruzani (1976) found less tolerance for frustration among subjects exposed to 30 minutes of continuous 80–85-dB (A) conglomerate noise than among subjects working in quiet. Sherrod, Hage, Halpern, and Moore (1977) found similar effects for 18 minutes of continuous exposure to 94-dB (A) conglomerate noise. Finally, Rotton et al. (1978) found that those exposed to 15 minutes of meaningful speech (two lectures on phobias) at 80 dB (A) had less tolerance for frustration following stimulus termination than did a no-speech (quiet) control group.

Attempts by Harris (Note 1) to replicate the poststimulation effects of unpredictable noise were less fruitful. Harris reported three studies, one in which he used noise [85–105 dB (A)] from an automobile horn and two in which he used a conglomerate noise of similar intensity. All three of the studies included both fixed and random-intermittent noise conditions and a quiet control group. Harris failed to find postnoise performance decrements on either proofreading (Experiments 1 and 2) or a serial search task (Ex-

periment 3). It should be noted, however, that the average level of proofreading performance for his subjects was very low in all conditions, which suggests a floor effect.

A failure to replicate the postnoise effect was also reported by Frankenhaeuser and Lundberg (1974). After exposure to 40 minutes of aperiodic bursts of 65-85-dB (A) conglomerate noise, subjects did not show less (or more) tolerance for frustration than after working on a task without noise or after relaxing. The tolerance for frustration score in this study was the time that a subject was willing to spend on an insoluble task after an obligatory period of 80 minutes on that task. It is likely that because of the long period of required work, this measure is considerably less sensitive than the Feather measure, which has no obligatory work period.

Two studies reported by Moran and Loeb (1977) similarly failed to find a noise after-effect. Participants were exposed to recordings of aircraft overflights [peaking at 90-105 dB (A)] that were either continuous or random-intermittent. A quiet experimental control group was also included. There were no effects of the noise (continuous or random-intermittent) on either the tolerance for frustration or the proofreading task. The authors pointed out, however, that it is possible that neither of the noise conditions in these two studies was actually unpredictable, since aircraft noise peaks were always signaled by onset of the overflight noise. This explanation is supported by later work from Loeb's laboratory (Percival & Loeb, in press, Experiment 2) in which decreased persistence on the tolerance for frustration task was found to occur after exposure to random-intermittent bursts of conglomerate noise and after exposure to random-intermittent bursts of aircraft noise peaks (eliminating the gradual onsets and offsets) but not following exposure to recorded normal aircraft flyovers (which include gradual onsets and offsets). There were no effects of any of the noise exposure manipulations on poststimulation proofreading performance.

DeJoy (Note 2) failed to find poststimulation effects of either random or fixed-intermittent 85-dB (A) print shop noise on either

a proofreading or an insoluble anagrams task. Since the anagrams task was affected by task load during noise (discussed later), it appears that this task was sensitive to a post-stimulation effect but that the noise failed to produce the effect.

Although the Glass and Singer (1972) work suggests that poststimulation effects occur only following unpredictable noise, two studies reported similar deficits following exposure to high-intensity, steady-state (no unpredictable components) continuous noise. Thus Hartley (1973) found deterioration of performance on a five-choice reaction time task following a 20-minute exposure to 100-dB (A) continuous broadband noise, as opposed to exposure to the same noise at 70 dB. Broadbent (1979) similarly exposed subjects to a broadband continuous noise of either 55 or 85 dB (C). The interference score on the Stroop Color-Word task was not affected by the sound level of the previous noise exposure. However, after noise, but not after quiet, subjects named patches of colored inks relatively faster than they read color names printed in black. Since both the Broadbent and the Hartley studies were primarily concerned with variations in sound level (there were no no-noise control groups), the effects they reported may depend on variations in intensity rather than on stimulus predictability (cf. Broadbent, 1977). This argument receives inferential support from Broadbent's (1979) failure to find effects of the high-versus low-intensity sound on Stroop interference, which has been reliably affected in those studies that compared an unpredictable noise condition to a quiet control group.

As is apparent from Table 1, nearly all of the studies that used steady-state continuous and variable continuous noise found post-stimulation deficits in performance. As mentioned previously, it is possible that the effect of steady-state continuous noise depends on variations in intensity, whereas that of variable continuous noise depends on variations in predictability. As is apparent from Table 2, results of studies of random-intermittent exposure are less consistent. Possible reasons for the failure of a number of these studies to replicate the Glass and Singer

Table 1
Nature of Noise Stimulus and Aftereffect Measures in Studies That Used Continuous Noise

Study	Description of noise	Performance aftereffects measure	Duration of noise	Sound level	Mode of delivery
Broadbent (1979)	Broadband, steady state	Stroop interference	20 min.	85 dB (C)	Speakers
Hartley (1973)	Broadband, steady state	Color naming/reading names of colors*	40 min.	100 dB (A)	Speakers
Rotton, Olszewski, Charleton, & Soler (1978)	Meaningful speech	Five-choice reaction time*	15 min.	80 dB (A)	Earphones
Sherrod, Hage, Halpern, & Moore (1977)	Conglomerate (with aperiodic bursts of electronic static)	Tolerance for frustration*	18 min.	94 dB (A)	Speakers
Wohlwill, Nasar, DeJoy, & Foruzani (1976)	Conglomerate (with aperiodic bursts of office noise)	Tolerance for frustration*	30 min	80-85 dB (A)	Speakers
Moran & Loeb (1977) Experiments 1 and 2	Aircraft sounds	Tolerance for frustration, proofreading	14.34 min.	90-105 dB (A) peaks	Not reported

* The noise described was associated with a deficit in performance on that aftereffect task.

(1972) work (particularly, Frankenhaeuser & Lundberg, 1974; Moran & Loeb, 1977; Harris, Note 1) have been presented earlier and are noted in Table 2. There appear to be no consistent differences between those intermittent noise studies that found aftereffects and those that failed to find aftereffects on the number of noise bursts, duration of noise exposure, percentage of the total period that they were exposed to noise, sound level, and whether the noise was delivered through ear-phones or speakers.

In sum, the data on poststimulation effects of noise on performance are consistent for variable continuous and steady-state continuous noise and mixed for intermittent exposure. The relative reliability of the poststimulation effect following continuous as opposed to intermittent sound may be attributable to the greater exposure time (noise on) in continuous noise studies. Nevertheless, if we confine ourselves to those studies that used clearly unpredictable noise and reasonably sensitive aftereffects measures, even the intermittent literature provides considerable support for the reliability of the postnoise effect.

Crowding. Those who study the effects of crowding on human behavior have found it useful to distinguish between two kinds of density—social density and spatial density (cf. Loo, 1973). Social density is manipulated by varying the number of people occupying a fixed quantity of space, and spatial density is manipulated by varying the available space but keeping the number of people constant. Since there is evidence that the effects of density are to some degree dependent on this distinction (e.g., Baum & Koman, 1976), the following review of the effects of high levels of density on poststimulation performance will similarly distinguish between these two kinds of density.

In an early study of the aftereffects of spatial density, Sherrod (1974) had groups of eight female high school students perform a number of tasks in either a large or a small room. After 1 hour of exposure, subjects were moved into a large reception area. Each student, at her own desk, was administered the tolerance for frustration and proofreading

tasks. Those subjects who had been working in high density (small room) showed less tolerance for frustration than did their low-density (large room) counterparts. There were no differences on the proofreading task.

Similar postcrowding deficits on the Feather tolerance for frustration task are reported by Evan's (1979) with mixed-sex groups of 10 persons and by Nicosia, Hyman, Karlin, Epstein, and Aiello (in press) for both male and female groups with 4 persons. The latter study, however, failed to find any poststimulation effects of high density on a visual search task and a problem-solving task. In a final study, Aiello, DeRisi, Epstein, and Karlin (1977) reported that following 30 minutes of sitting in a room with 3 other subjects, female undergraduates who were crowded (small room) scored lower on two measures of creativity than did their uncrowded (large room) counterparts. In sum, all four of the existing studies of the aftereffects of spatial density reported poststimulation effects.

There are two studies of the poststimulation effects of social density. The first was conducted by Saegert, Mackintosh, and West (1975, Experiment 2) in a railroad station in midtown Manhattan. Male and female subjects were asked to do a number of tasks during a crowded or uncrowded time of day. After task completion, the subject was brought to a quiet secluded place and administered the Stroop Color-Word task. Whereas females who had been exposed to high levels of density performed more poorly on the Stroop than did their low-density counterparts, males performed better after high- than after low-density exposure. Although other studies have found interactions between density and gender on a number of dependent measures (see Sundstrom, 1978, for a review), the relationship between one's gender and whether one experiences stress in a particular high-density setting is still unclear. As a consequence, we do not know whether it is the males or the females who are experiencing stress in this situation, and thus it is impossible to determine whether these data indicate a poststress effect.

In a study by Dooley (1978), groups of

Experiment 1	Auto horn	Proofreading	30	3.8 min.	12.5	85-105 dB (A)	Not reported	Possible floor effect on proofreading in Experiments 1 and 2
Experiment 2	Conglomerate	Proofreading	30	3.8 min.	12.5	85-105 dB (A)	Not reported	
Experiment 3	Conglomerate	Serial search	30	3.8 min.	12.5	85-105 dB (A)	Not reported	
Moran & Loeb (1977) Experiments 1 and 2	Aircraft overflights	Tolerance for frustration	14	4.6 min.	29	90-105 dB (A)	Not reported	Aircraft noise peaks were always signaled by the onset of overflight noise

^a The noise described was associated with a deficit in performance on that aftereffect task.

^b A proofreading effect was found in all but one study (Glass & Singer, 1972, p. 80).

^c Decreased tolerance for frustration occurred following aircraft overflight peaks and conglomerate noise but not following aircraft overflights and white noise.

either three or nine male undergraduates performed a simulated marketing task in a small room. In an experimental control group, a single subject performed the same task alone. After task completion subjects were moved to individual cubicles in which they were administered a proofreading task. Results indicated that the poststimulation effects in this study were mediated by individual differences in personal space needs. Both high- and low-density conditions (as opposed to the alone condition) had a negative impact on the proofreading quality of subjects with far (need more) personal space but not on those with close (need less) personal space. It appears that the mere presence of others in the small room, rather than the manipulated level of high density, acted as the stressor in this study. Moreover, those subjects who were most likely to experience stress when involved in close interactions with others (i.e., those with far personal space) showed aftereffects. Those less likely to experience stress (i.e., those with close personal space) did not show the effects. In sum, there is evidence for a postdensity effect in cases in which the close presence of others is likely to be experienced as stressing.

Task load. Three studies have indicated that subjects who experience a high task load perform more poorly following task completion than those assigned a low task load. Thus Coben and Spacapan (1978, Experiment 1) found in a four-choice reaction time experiment that those required to respond to 100 lights per minute had less tolerance for frustration following task completion than those responding to 50 lights per minute. There were, however, no effects of task load on proofreading performance. (This experiment controlled for subjects' perceptions of success-failure and thus is not explicable in those terms.) Hartley (1973) reports that those required to perform a serial reaction time task for the first 20 minutes of the experiment performed more poorly on the same task in the last 20 minutes than those who read during the initial stage of the study. (This effect may, of course, be attributable to boredom on the part of those required to perform the same task twice.) Similarly, Rot-

ton et al. (1978) found that the expectation that one would be required to recall a speech, even though one was never actually required to do so, resulted in lower tolerance for frustration following task completion than for those not expecting a recall test. DeJoy (Note 2), however, found no differences in tolerance for frustration (insoluble anagrams task) or proofreading following performance of a high- versus a low-load coding task.

Other social and nonsocial stressors. Glass and Singer (1972) also reported that poststimulation deficits in performance occur following electric shock, a frustrating experience with a bureaucracy, and an experience of arbitrary or sex discrimination. In the electric shock study (Glass & Singer, 1972, p. 110) those subjects exposed to unpredictable and uncontrollable shock performed more poorly on both the Stroop and proofreading tasks following exposure. A later study (Glass et al., 1973), found similar poststimulation effects of electric shock on the Stroop. Experiences of bureaucratic harassment (Glass & Singer, 1972, p. 124) similarly resulted in poorer proofreading for the harassed than for the nonharassed groups after the experience had ended, and the study of the effects of discrimination in the amount of pay received for participating in the experiment (p. 132) found that those who experienced discrimination performed more poorly on the Stroop following the experience than those who did not experience discrimination.

Conclusions. The previously cited studies provide evidence for both the reliability and generality of the poststimulation effect of stress on performance. These effects have appeared in the vast majority of studies, and these studies have used a wide range of stressors. The data suggest that the effect is most likely to occur when the stressor is clearly unpredictable and when a sensitive aftereffects measure is used. Moreover, factors that might mediate the stressfulness of the situation (e.g., subject gender and need for personal space in the social density studies) are important determinants of whether a particular manipulation will produce an aftereffect. The most reliable mea-

asures appear to be those used by Glass and Singer (1972), although the proofreading task has proved less reliable (e.g., Cohen & Spacapan, 1978; Glass & Singer, 1972, p. 80; Sherrod, 1974) than the Feather and Stroop tasks. The inconsistency of the proofreading measure may be attributable to the large variation among subjects' literary skills that often results in substantial error variance on proofreading scores. Although other measures have only been used in individual studies, poststimulation effects have been obtained on a serial reaction time task (Hartley, 1973) and a creativity task (Aiello et al., 1977). Aftereffects measures that have failed include visual search tasks (Nicosia et al., in press; Harris, Note 1) and a problem-solving task (Nicosia et al., in press). Since in all of the Glass and Singer studies and replications, the poststimulation tasks were administered shortly after stressor termination, there are no data on the time course of the effect.

Predictable Versus Unpredictable Stressors

Glass and Singer reported five studies that compared the poststimulation effects of predictable versus unpredictable noise. The first two studies (Glass et al., 1969, Experiment 1; see also, Glass & Singer, 1972, pp. 47, 52) compared fixed versus random-intermittent exposure to a broadband conglomerate noise made up of a number of fairly typical urban sounds. In both of these studies, those exposed to unpredictable noise performed more poorly than did the predictable noise group on both the tolerance for frustration and proofreading tasks. There was no difference between poststimulation performance of the predictable noise group and a no-noise control group. The first study also indicated that predictability of the noise was a more important determinant of poststimulation effects than was the intensity (56 vs. 108 dB) of the sound. In a third study (Glass & Singer, 1972, p. 55) predictability was manipulated by the use of signaled (by a light) versus unsignaled (light occurrence is random) noise bursts. Again, those exposed to unpredictable noise were less persistent on insoluble puzzles administered after noise

termination. The effect of unpredictable noise on proofreading was, however, not replicated.

Predictability was manipulated in two other studies that were primarily designed to assess the effect of inhibiting adaptation on post-stimulation effects. (See the section on Adaptive-Cost Hypothesis under Theory Review.) The first study was the only one in which Glass and Singer (1972, p. 141) reported a clear reversal of the predictability effect. For subjects working on difficult math problems during exposure, higher frustration tolerance and better proofreading occurred in the random-intermittent condition than in the fixed-intermittent condition. This was not true for those working on simple problems. The second study (Glass & Singer, 1972, p. 147) resulted in the usual predictability effect with those who were exposed to random-intermittent noise, whether the interburst intervals were 51 sec or 96 sec, performing more poorly on the proofreading task than those who were exposed to fixed-intermittent bursts.

Gardner (1978, Study 1, Table 1) similarly presented subjects with fixed or random-intermittent conglomerate noise of 100 dB. A proofreading task performed after noise exposure was performed more poorly by those exposed to unpredictable than by those exposed to predictable noise. Likewise, Percival and Loeb (in press) reported that subjects exposed to 24 minutes of 95-dB random-intermittent conglomerate noise showed less tolerance for frustration following exposure than either those exposed to equivalently intense fixed-intermittent sound or those exposed to a soft (46-dB) broadband sound. Studies by Harris (Note 1), Moran and Loeb (1977), and DeJoy (Note 2) described earlier also manipulated the predictability of the noise. As mentioned earlier, none of these investigations indicated aftereffects of either predictable or unpredictable sound.

In sum, the role of predictability in producing stress aftereffects has not received considerable attention since the publication of the Glass and Singer book. Existing evidence does, however, suggest that aftereffects are more likely to occur following exposure to the unpredictable rather than a predictable stressor.

Controllable Versus Uncontrollable Stressors

Glass and Singer (1972) reported a number of studies which indicated that the after-effects of stress occur following uncontrollable but not controllable stressors. First, there were two identical studies (pp. 64, 65) that used 108-dB aperiodic noise in which half of the subjects were instructed how to terminate the noise by pressing a button (perceived control). In fact, the perceived control subjects did not actually terminate the noise. In both studies, following noise exposure, those provided with perceptions of control over stimulus termination had more tolerance for frustration and performed better on the proofreading task than did their counterparts without perceptions of control.

In a third study, Glass and Singer (1972, p. 69; see also, Glass, Reim, & Singer, 1971) tested the proposition that indirect control (i.e., having access to another person who could terminate the noise) would be similar to having direct control over noise termination. Their hypothesis was confirmed. Following exposure to the 108-dB conglomerate noise, those with indirect control performed better than those lacking the perception that they (or their partner) could control the termination of the noise. In a final study, Glass and Singer (1972, p. 74) found that knowing that someone else was able to terminate the noise (for themselves) during the experiment but that one's own exposure could not be terminated (relative deprivation) did not increase poststimulation effects. However, as in previous studies, a proofreading task administered after stimulus termination was performed more poorly by those lacking perceived control than by those with control.

A replication of the aftereffects of noise that used a slightly different operation of perceived control is reported by Gardner (1978). An inability to replicate Glass and Singer when using an informed consent form that explicitly informed the subject that he or she could leave the experiment without loss of pay led Gardner to use the informed consent form as a way of manipulating control. Gardner reported that although it was impossible to replicate the aftereffects of unpredictable, uncontrollable noise with in-

formed consent, the effect was replicable when informed consent was not required. Unfortunately, those who received the informed consent were not only given the perception of control over termination of the stressor (i.e., they could leave at will) but also were making an explicit choice (to the extent of signing their names) to participate in the study prior to noise exposure. Thus, it is unclear whether the ameliorative effects of informed consent in this study are attributable to increased control or to increased choice and commitment.

Perceived control over the termination of the stressor was also examined in the previously described study of spatial density by Sherrod (1974). Besides the high-density (small room) and low-density (large room) conditions, an additional condition was included in which subjects were assigned to a high-density setting but were told that they could leave the room and work in a larger room if they so desired (density with perceived control). As in the noise studies, the perceived control subjects did not actually use this option. The high-density group showed the least persistence on the insoluble puzzles, followed by an intermediate level of persistence by those high-density subjects with perceived control, and finally, the most persistence was shown by the low-density group. As mentioned earlier, there were no effects on the proofreading task.

The previously described studies all provided subjects with the perceived ability to terminate the stressor, but in all cases subjects did not actually perform any coping responses. That is, they knew they could terminate the stressor but did nothing about it. A slightly different form of control was offered to subjects in a study of the after-effects of electric shock reported by Glass et al. (1973). During an initial trial block, all of the subjects received a series of 10 6-sec shocks and were required to press a reaction time key at the onset of each shock. During a second block of trials, the perceived control group was told that they could decrease the duration of each shock (from 6 to 3 sec) by maintaining a fast reaction time to the onset of the shock. For half of these sub-

jects, all shocks were halved (perceived control with reduction), and for the remaining subjects none of the shocks were halved (perceived control without reduction). Two experimental control groups received shocks of either 3 sec (no perceived control with reduction) or 6 sec (no perceived control without reduction) but were given no indication that shock duration was related to their behavior. Thus in this case, subjects with control were actually implementing that control by attempting to maintain fast reaction time. Performance on the Stroop, administered after the two blocks of shock trials were completed, indicated that subjects who were told that they could control the duration of the shock and ostensibly succeeded in doing so (perceived control with reduction) performed better on the Stroop than both of the no-perceived-control groups and better than the group given the expectancy that control was possible who actually failed to control (perceived control without reduction).

A number of studies of the learned helplessness phenomenon have also examined the effects of implemented control over a stressor on poststress performance. Compared with those with the ability to escape or avoid loud noise, those lacking control subsequently performed more poorly on anagrams (Gatchel, McKinney, & Koebernick, 1977; Hiroto & Seligman, 1975), a concealed figures test (Krantz & Stone, 1978), and a proofreading task (Krantz & Stone, 1978). In contrast to the previously described studies, subjects in the unavoidable, unescapable stress conditions in these studies experienced failure as well as stress. (The unavoidable stress conditions in these studies are similar to the perceived control no-reduction condition in the study by Glass et al., 1973, described previously.) The fact that control and success-failure are confounded in these studies makes it difficult to assess whether the mechanisms involved are the same as in the other aftereffects work (cf. Cohen, Rothbart, & Phillips, 1976; Griffith, 1977).

Two recent studies of helplessness induced by exposure to uncontrollable bursts of noise (tones) provide data that are inconsistent with those reported in the aftereffects litera-

ture (Gatchel, Paulus, & Maples, 1975; Gatchel & Proctor, 1976). Both of these studies included an experimental control group in which subjects were instructed to merely sit and passively listen to loud tones (no success or failure). This condition is similar to an unpredictable, uncontrollable stressor condition in the aftereffects paradigm and thus would be expected to result in poststimulation deficits in performance. Although a learned helplessness group, who thought they could escape the noise but actually could not, showed poststimulation deficits on an anagram task, the group who passively listened to the tones did not show deficits. The noise dose in these experiments, however, was small in comparison with previously cited noise studies.²

The research discussed previously has been limited to studies that provided control over the termination of a stressor. A study of the aftereffects of noise by Sherrod et al. (1977) extended this work by investigating the relative contribution of control over initiation of the stressor as well as over termination. Subjects with initiation control were allowed to choose whether they would be exposed to noise. The experimenter stressed, however, that for the purposes of the study, he would prefer that they turn the noise on (they all did). Subjects without initiation control were given no such choice. Termination control was provided in the same way as in the Glass and Singer studies. Following noise exposure the Feather task was administered. Sherrod and his colleagues reported that the least

² At the beginning of both of these studies, the subject, after hearing a sample tone, was offered the opportunity to withdraw from the experiment. As we outline later in this article, such a choice, by providing a form of control over the situation, is likely to ameliorate any poststimulation effects (cf. Sherrod et al., 1977). If we assume that the learned helplessness effect in these studies was a response to failure and not to a lack of control, it is possible that the ability to choose whether to participate in the study ameliorated control-related effects for the passive listening group but did not affect the learned helplessness (failure) group. Admittedly, however, these studies constitute an additional failure to replicate postnoise effects, and this post hoc explanation must be viewed as only tentative.

tolerance for frustration was shown by those who lacked any kind of control over the noise, intermediate tolerance was shown by those with initiation control, termination control caused an even greater increase in tolerance, and combined control (both initiation and termination) caused the greatest increase. Thus although initiation control was not as effective as termination control, increasing overall perceptions of control by combining initiation and termination was the most effective intervention.

In a field study of the stress involved in donating blood, Mills and Krantz (1979, Experiment 1) investigated the roles of providing information about a threatening event and of providing choices about that event in mediating poststress response. Information and choice were both conceptualized as forms of personal control because they presumably allow one to alter or affect their outcomes. In this study, blood donors were offered or not offered a choice of which arm blood would be drawn from. This manipulation offers some control over the procedure but not directly over either the initiation or termination of the stressor. Also, although all donors received some information prior to the procedure, in half of the cases (high information) this information dealt with the details of the procedure and the sensations the donor might expect, whereas in the remaining cases (low information) the information was limited to a general description of the Red Cross blood donor program. The Stroop Color-Word test was administered during the donor recovery period. There were no differences between conditions in Stroop performance. However, the authors pointed out that the nursing interventions during the procedure and the refreshments given to donors following the procedure precluded an adequate assessment of aftereffects in this setting. In addition, the time that elapsed between the stress experience and the aftereffects measure was long in comparison with previously discussed studies in which the aftereffects measures were administered either immediately or after a short respite.

A laboratory study of cold stress by the same authors (Mills & Krantz, 1979, Ex-

periment 2) similarly manipulated information about the stress experience and choice of hand to be placed in the cold water. In this case, however, those who were allowed to choose the hand to be used could also elect to remove their hand from the cold water if they chose to do so. The proofreading measure was administered following stressor exposure. Subjects with choice of hand and perceived control over stressor termination (high choice) were more accurate proofreaders than those given neither choice nor the perception of control (low choice). Also under low-choice conditions, providing information led to improved performance, whereas under high-choice conditions, providing information made little difference. It appears that in this case combining two forms of control did not further decrease poststress effects. It should be pointed out, however, that the high-choice condition itself involved two forms of control (hand choice and immersion time in cold water). Thus, it might be more accurate to conclude that the addition of a third form of control did not decrease poststress effects.

In a final study, DeJoy (Note 2) compared posttask performance of subjects who had some control over a difficult coding task (self-paced) with the performance of subjects who lacked task control (experimenter-paced). The two conditions were yoked (average stimulus exposure time of self-paced subject used for experimenter-paced subject) to equate conditions on time on task. Experimenter-paced subjects performed more poorly on an insoluble anagrams task (tolerance for frustration) administered immediately following completion of the coding task than did self-paced subjects. There were no effects on the proofreading task.

Conclusions. The data are almost unanimous in supporting the role of both perceived and implemented control over termination of a stressor in ameliorating stress aftereffects. In some cases those groups with control performed as if they were not exposed to a stressor (e.g., Gardner, 1978; Glass et al., 1973), whereas in others (e.g., Sherrod et al., 1977) control provided some improvement in poststress task performance but did not com-

pletely ameliorate the effect. The single study of initiation control similarly suggests a lessening in poststress performance deficits. Initiation control does not, however, appear to be as effective as termination control. There is also some mixed evidence that providing subjects with choice over an aspect of the stress situation and/or with information about the procedure and expected sensations similarly lessens the poststimulation impact of the stressor.

Is providing someone with more than one kind of control a more powerful intervention than providing them with a single mode of control? The combination of initiation and termination control does prove to be more effective than either of these modes alone (Sherrod et al., 1977). However, the combination of two kinds of choice and one kind of information control does not seem to be more effective than either of these modes alone (Mills & Krantz, 1979). It could be that combined modes of control do help to reduce poststress performance deficits until one reaches levels equivalent to performance following no-stress conditions (as in the Sherrod et al., 1977, study), but additional control is unimportant if that level is already reached (as in Mills & Krantz, 1979).

The research clearly demonstrates that providing one with increased control over a stressor or over a stress setting decreases deficits in poststimulation performance. None of the reviewed studies, however, have investigated whether increased control over a setting is beneficial when there is no stressor present. (This assumes that the demanding coding task used in the DeJoy, Note 2, study was experienced as a stressor.) That is, since none of these studies included a condition that provided control over a nonstressing setting (e.g., perceived ability to leave if the experiment is not fun or choice of task or task order on a simple task), it is unclear whether there is an interaction between stress and control or a main effect for control. Since there is some evidence that perceived control over a simple task setting may improve performance in that setting (Perlmutter & Monty, 1977), an overall rather than stress-specific effect of control does seem possible.

Aftereffects on Social Behavior

Recent studies on the poststimulation effects of uncontrollable stress on social behavior have extended the scope of the original aftereffects research. For example, two studies have reported decreased poststimulation helping after exposure to unpredictable, uncontrollable stress. In an experiment by Sherrod and Downs (1974), subjects performed a task while listening to either a recording of a soothing simulated seashore or a stressing recording of dixieland jazz plus a male voice reading nonrelevant prose. In a third condition subjects listened to the stressing tape but were told that they could terminate the distracting stimulus if they wished (perceived control). After the completion of the 20-minute experiment, subjects left the laboratory and were confronted by a second experimenter who asked for voluntary help in pretesting some experimental materials. Subjects who listened only to soothing seashore sounds volunteered the most times, followed by subjects who listened to the stressing tape but who had perceived control, followed finally by stress-without-control subjects. Thus, exposure to uncontrollable stress decreased poststimulation helping with the addition of control over the termination of the noise partially ameliorating these effects.

Similar results were found in a study of the aftereffects of density and task load conducted in a large shopping center (Cohen & Spacapan, 1978, Experiment 2). Subjects were required to perform high- or low-information rate shopping tasks during periods in which the shopping center was crowded or uncrowded. After completing their task, subjects (on their way to meet the experimenter) entered a deserted corridor in which they encountered a woman who feigned dropping a contact lens. Those subjects who performed high-load tasks and/or were crowded helped less often and for less time than their low-task-load, uncrowded counterparts.

Increased aggressive behavior following exposure to uncontrollable stress was reported by Donnerstein and Wilson (1976). In their experiment, subjects completed a math task under either quiet, high-intensity noise or

high-intensity noise with perceived control over the termination of the noise. Following noise exposure, half of the subjects were angered (by the person they would later aggress against) and half of the subjects were not angered. Angered (but not nonangered) subjects with no control revealed an increase in aggression, whereas the level of aggression of perceived-control subjects was no different than that of no-noise subjects.

Three studies described earlier also used poststress measures of social behavior. Thus Rotton et al. (1978) found that both loud speech and the combination of conglomerate noise and a taxing task reduced one's ability to differentiate among people occupying different roles. Epstein and Karlin (1975) reported that groups of men who were crowded were less cohesive and more competitive following the stress experience. Women, however, were more cohesive and less competitive following the crowded versus noncrowded experience. Finally, Dooley (1978) failed to find any relationship among social density, volunteering for a future experiment, or rating of attractiveness of same-sex persons.

Overall, it appears that exposure to unpredictable and uncontrollable stress is followed by a decreased sensitivity to others. This includes a decrease in helping, a decrease in the recognition of individual differences, and an increase in aggression.

Naturalistic-Correlational Studies of Aftereffects

A number of recent studies have investigated the impact of living and/or working in a stressful environment on task performance and social behavior outside of the stressing environment. For example, several investigators have examined the effects of prolonged exposure to community noise on the performance of elementary school children. In one study, Cohen, Glass, and Singer (1973) tested children living in apartment buildings built on bridges spanning a busy expressway. When tested in a quiet setting, children who lived in noisier apartments showed greater impairment of auditory discrimination and reading ability than did those who lived in quieter apartments. The length of residence increased

the magnitude of the correlation between noise and auditory discrimination. Additional analyses ruled out social class variables and hearing losses as possible explanations. A study of children attending school in the air corridor of a busy metropolitan airport (Cohen, Evans, Krantz, & Stokols, 1980) indicated that children living and attending school in the air corridor were poorer on both a simple and a difficult puzzle-solving task and were more likely to give up on the task than their quiet neighborhood counterparts. Again, there were controls for social class and for hearing damage. Unlike the apartment noise study, this study did not find that children from noisy environments (schools) had poorer verbal abilities.

A study of 4½- to 6½-year-old children from homes described by their parents as either noisy or quiet similarly suggests poorer post-stimulation task performance on the part of children from noisier homes (Heft, 1979). The children performed a simple matching (visual search) task and then were administered a recall test for some of the incidental stimuli in that task. Children from noisy homes performed more poorly on both the matching and incidental memory tasks than those from quieter homes. Performance on a second matching task indicated similar deficits for children from noisy as opposed to quiet homes. Analyses controlled for age, preschool experience, and income level of parents. It should be noted, however, that self-reports of noise level do not usually correlate highly with objective noise measures (cf. Kryter, 1970) and thus limit the generality of these findings.

Two naturalistic investigations of crowding also suggest effects that occur outside of the stressing environment. Baum and Valins (1977) reported a number of studies of the behavior of dormitory residents who, because of dormitory design, were exposed to prolonged and repeated personal encounters with large numbers of other residents (long-corridor residents) versus those whose forced encounters included a comparatively small number of others (short-corridor and suite residents). Under controlled conditions outside of the dormitory, those who had a large

This Page Intentionally Left Blank.

This Page Intentionally Left Blank.

number of personal encounters showed less group consensus after a discussion, sat further away from, spent less time looking at, and initiated fewer conversations with a stranger (confederate), used a withdrawal strategy more often in a prisoner's dilemma game, and were less likely to assert themselves by asking questions in an ambiguous situation.

Two studies reported by Rodin (1976) similarly suggest aftereffects of residential density. In the first study 6-9-year-old children from high-density apartments of a low-income housing project were less likely than children from less dense homes from the same project to control (choose) their own outcomes. In a second study, eighth-grade children from high-density apartments were more adversely affected by a learned helplessness pretreatment—insoluble puzzles—than were their low-density counterparts. These effects persisted even after statistical control for social class and race were used.

The studies discussed previously suggest that prolonged exposure to a stressor is associated with a number of poststimulation effects on performance and social behavior. Although it is likely that some of these effects are specific to the stressor (e.g., the tendency of those who are forced into constant contact with others to avoid strangers in the Baum and Valins work), a number of the studies indicate a more general helplessnesslike effect (Baum & Valins, 1977; Cohen et al., 1980; Rodin, 1976). It is important to emphasize that these studies are all correlational and thus do not allow causal inference.

The Meaning of the Stressor and the Meaning of the Control Manipulation

Although the data on the effects of uncontrollable stressors on poststimulation performance and social behavior is reasonably consistent, there have been a number of published and unpublished² failures to replicate these effects. These inconsistencies are probably inevitable given the complexity of the situation being presented to a subject. First, it is likely that our responses to loud noise and to other potentially stressing stimuli are

mediated by cognitions other than control, and we may often unintentionally invoke such cognitions in our laboratories. For example, Cohen (in press) has outlined a number of situational characteristics of laboratory settings that may affect the meaning of the potential stressor for the subject and consequently, whether it will produce stress-related responses. Among others, these factors include (a) whether the participants in the study are aware that the exposure to the aversive stimulus will last for only a short period (cf. Altman, 1975), (b) the salience of the implied contract between the experimenter and the subject that suggests no harm will come to the subject during the experimental procedure, (c) whether the subject chose to participate in the study and whether an informed consent slip was signed.

Averill (1973) has pointed out that the stress-reducing properties of a personal control intervention similarly depend on the meaning of the control response for the individual. Thus telling a subject that pressing a button will terminate a loud noise may or may not suggest that he or she has control over the termination of the stressor. One alternative interpretation of this intervention might be that the stressor must be pretty dangerous if the experimenter needs to provide an escape mechanism.

Theory Review

Adaptive-Cost Hypothesis

Glass and Singer's (1972) working hypothesis was that the process of adaptation requires cognitive work. This work included searching for appropriate coping responses and/or attempting to redefine the stimulus. Moreover, they assumed that the work required to adapt to unpredictable and uncontrollable stressors was substantially greater than that required to adapt to predictable and controllable stimulation. According to Glass and Singer, the adaptive-cost hypothesis predicts that poorer performance on aftereffects tasks should vary directly with degree

² Unpublished research conducted in my own laboratory. (See, also, Baddeley, Note 3; Evans, Note 4; Stokols, Note 5.)

of adaptation, since a greater degree of adaptation implies a greater amount of adaptive effort. Presumably, increased adaptive effort would deplete one's available psychic energies and would thus result in deficits on subsequent demanding tasks.

Glass and Singer (1972) presented two arguments that led them to discard this hypothesis. First, they assumed that decrements in galvanic skin response (GSR) to noise and shock are valid indices of the cognitive effort involved in adaptation. This follows from their assumption that the greater the adaptation, the greater the amount of adaptive effort. There were no significant correlations between aftereffects scores and indices of GSR adaptation for subjects in various conditions. Thus there was no evidence for differential cognitive work. Second, they assumed that a situation in which one was exposed to unpredictable stress but in which adaptation was inhibited would not result in poststimulation effects. This should be true, since a lack of adaptation implies a lesser degree of adaptive effort. They were successful in inhibiting physiological adaptation in two studies (pp. 141-153) but found poststimulation effects even in the conditions in which subjects did not physiologically adapt. They thus concluded that "it is not the adaptive process that causes adverse aftereffects" (p. 153).

Although the authors describe the effort of adaptation as a cognitive process of searching for appropriate coping strategies and of redefining the stimulus, they take physiological evidence based on one index of autonomic response as the measure of adaptation. Existing knowledge concerning the relationship between cognition under stress and corresponding physiological fluctuations is equivocal at best (cf. Kahneman, 1973). Moreover, it is likely that those subjects who were prevented from physiologically adapting worked just as hard (if not harder) to cope with and redefine the stressor. In other words, it is possible that a significant amount of effort may be expended even if adaptation does not occur. Thus, aftereffects may occur because of the adaptive process even when adaptation fails. In sum, although the Glass

and Singer (1972) data do not provide support for the adaptive-cost hypothesis, neither do they provide convincing evidence to justify its rejection. Unfortunately, none of the more recent studies have attempted direct tests of this explanation.

Information Overload

An alternative form of a psychic cost hypothesis was recently proposed by Cohen (1978). He argued that unpredictable, uncontrollable stressors, because they are potentially threatening, substantially increase demands on attentional capacity. This increased demand might occur because individuals are required to continually monitor potentially threatening stimuli to evaluate their adaptive significance and to decide on appropriate coping responses (cf. Lazarus, 1966). Increased demand may also occur because of effort required in tuning out or inhibiting response to the distracting stimulus. Cohen further suggested that an individual's attentional capacity is not fixed but shrinks when there are prolonged demands. This shrinkage or *cognitive fatigue* presumably increases with both the attentional load of an activity and the duration of an activity. Thus prolonged exposure to an environmental stressor and/or to a high information rate task should result in cognitive fatigue—an insufficient reserve of attention to perform demanding tasks.

What are the implications of the cognitive fatigue hypothesis for the performance of ongoing and subsequent tasks? Task duration under experimental conditions is usually limited to between 20 minutes and an hour. Although this may be sufficient to cause a significant decay in available capacity, it may not affect performance on an ongoing task that by that point is well practiced and requires little effort. Subsequent tasks, however, that demand considerable attention on the part of the subject would be sensitive to fluctuations in available processing capacity. Thus we would expect depletions in attentional capacity resulting from prolonged task and environmental demand to be manifest in deficits on difficult tasks administered immediately after termination of the principal task.

Three recent studies (mentioned earlier) have provided direct support for the cognitive fatigue hypothesis. All three suggested that those experiencing a high task load perform more poorly on subsequent tasks than those experiencing lower task loads. For example, Hartley (1973) reported that both increased task load and increased noise result in poorer performance on a subsequent serial reaction time task performed in quiet. Moreover, there is an additive effect of task load and noise on poststimulation performance. Rotton et al. (1978) similarly reported that deficits on the Feather tolerance for frustration task increase with both task load of a previous task and the addition of noise to that task. Again, there is an additive effect when these conditions are combined. In a final study, Cohen and Spacapan (1978, Experiment 1) reported that deficits on the tolerance for frustration task (but not on the proofreading task) increased as task demand and task duration of a previously performed task increased. Moreover, self-reports of mental fatigue similarly increased with both task load and task duration. Thus subjects' self-perceptions were consistent with both the predictions of the cognitive fatigue hypothesis and the data from the tolerance for frustration task.

A study reported by Wohlwill et al. (1976) is not, however, consistent with the cognitive fatigue hypothesis. They reported that subjects who listened to noise but did not perform a concurrent task showed the same aftereffects as those who worked on a task while listening to noise. Since performing a task under noise should demand greater attentional capacity than merely being exposed to the noise, the cognitive fatigue hypothesis would suggest that the noise plus task condition would show a greater magnitude of aftereffects. Interpretation of this study is difficult, however, since the no-task subjects were given instructions that may have led them to assume that they were expected to process (possibly remember) task stimuli. Unfortunately, the investigators did not administer any self-report measures of cognitive fatigue or ask subjects how they perceived the experimental situation.

Cohen also suggested that posttask (or poststress) attentional deficits can have detrimental effects on interpersonal behavior. He argued that lacking adequate attention reserves, an individual sets priorities for use of his or her attention. The most common strategy is to focus available attention on inputs most relevant to one's own goals, neglecting other cues, social and nonsocial alike (cf. Milgram, 1970). Important social cues that are often neglected when attention is restricted include those that carry information concerning the moods and subtly expressed needs of others. The neglect of such cues results in a lowered probability of helping another, expressing sympathy for another, or reacting appropriately to another's needs. Other proposed social consequences of attentional focusing following high attentional demand include oversimplification and distortion in the perception and evaluation of communications and persons.

Evidence for the contention that conditions leading to cognitive fatigue will result in less sensitivity to others comes from a number of recent studies. In a study conducted in a field setting (Cohen & Spacapan, 1978, Experiment 2), after performing a high-load shopping task, subjects were less likely to help a woman search for a contact lens than their counterparts who performed a low-load task. Similarly, subjects who had been crowded were less likely to help than those who had not been crowded. Again, there is an additive effect in the high task load, high-density condition. Rotton et al. (1978) reported increased difficulty in differentiating between people who occupy different roles following both increased task load and noise exposure. Thus it appears that poststimulation task deficits and insensitivity to social cues can be induced by manipulation of task load as well as by unpredictable stress. Previously cited studies on poststress aggression (Donnerstein & Wilson, 1976) and poststress helping (Sherrod & Downs, 1974) can be similarly viewed from this perspective.

Learned Helplessness Theory

Glass and Singer (1972; see, also, Seligman, 1975) suggested that aftereffect deficits

are attributable to learned helplessness. They argued that subjects who are unable to predict and control a stressor learn that their reinforcements are independent of their responses, which results in motivational decrements that are manifested in poorer performance on poststimulation tasks. Such an interpretation requires at least two assumptions: (a) Learned helplessness can be induced when performance on the experimental task (task performed during stressor exposure) is not instrumental in escaping or avoiding the aversive stimulus; and (b) helplessness will generalize to a wide range of cognitive tasks, including tasks that do not require a direct problem-solving strategy. (Test tasks used in learned helplessness studies usually require subjects to initiate responses in a trial-and-error fashion; cf. Wortman & Brehm, 1975.)

Evidence relevant to this last assumption has been reported by Cohen et al. (1976). These authors found that task impairment on the Glass and Singer aftereffects tasks can be replicated when a more standard learned helplessness pretreatment is used. Employing a pretreatment used by Roth and her colleagues (e.g., Roth & Bootzin, 1974) in previous studies, Cohen et al. found that subjects who received noncontingent reinforcement showed deficits on the tolerance for frustration and the Stroop color word task similar to the deficits found by Glass and Singer for subjects exposed to uncontrollable noise. Further support for the helplessness explanation is provided by a study by Glass and Singer (1972) in which subjects who were told that solving experimental puzzles would terminate the noise, but who actually received insoluble puzzles, took more time to solve a final puzzle that was soluble than those subjects who had been working on soluble puzzles and perceived that they were shortening noise exposure (p. 89). Both of these studies confounded controllability and success-failure. (Cohen et al. did attempt to minimize this effect by yoking the contingent and noncontingent groups on number of reinforcements and number of trials.) As mentioned earlier, a number of learned helplessness studies involved the administration of

escapable or unescapable noise. However, since controllability and success-failure are also confounded in these studies, it is unclear whether they are appropriate analogs of the aftereffects paradigm.

The strongest source of support for the learned helplessness interpretation comes from the naturalistic studies of stress aftereffects. Work in crowded college dormitories (Baum & Valins, 1977), in high-density low-income housing (Rodin, 1976), and in schools located in the air corridor of a busy urban airport (Cohen et al., 1980) all suggested that those living under environmental stress show behavioral manifestations of helplessness.

Although the above data lend support to the helplessness hypothesis, there are recent data that call the helplessness interpretation into question. Seligman (1975) argued that a major consequence of experience with uncontrollable events is motivational—undermining the motivation to initiate voluntary responses that control other events. One manifestation of the motivational deficit is that “helplessness retards the initiation of aggressive as well as defensive responses” (Seligman, 1975, p. 33). A study by Donnerstein and Wilson (1976), however, indicated that after stimulation is terminated subjects who lack control over noise are more (not less) likely than subjects with perceived control over the noise to shock a person who angers them.

The helplessness interpretation is especially compelling because it provides an obvious explanation for poststimulation effects on the extremely reliable Feather task. That is, less persistence on a difficult task is characteristic of helplessness. It is, however, difficult to explain why increased task load would lead to helplessness, especially when success feedback is held constant across conditions (Cohen & Spacapan, 1978, Experiment 1). Moreover, helplessness is accompanied by a relatively negative affective state (Gatchel et al., 1975; Miller & Seligman, 1975; Pittman & Pittman, 1979; Seligman, 1975). Yet aftereffect studies generally reported no differences between conditions in reported affect following stressor exposure (e.g., Cohen & Spacapan, 1978;

Glass & Singer, 1972; Mills & Krantz, 1979, Experiment 2; Pennebaker, Burnam, Schaeffer, & Harper, 1977; Wohlwill et al., 1976). In addition, the overall mood tone of subjects in all conditions is sometimes positive (e.g., Cohen & Spacapan, 1978; Wohlwill et al., 1976).

Arousal Theory

A number of investigators have mentioned the possible role of arousal in producing after-effects (e.g., Evans, 1978; Glass & Singer, 1972; Poulton, 1978). The most popular form of this theory assumes that those exposed to uncontrollable and unpredictable stressors show higher levels of arousal immediately following exposure than those exposed to predictable and/or controllable stressors. How would increased arousal affect poststimulation task performance and social behavior? It is generally believed that there is an optimal level of arousal for performance of a particular task (cf. Poulton, 1970). Performance increases with increments in arousal up to that optimal point and decreases as the arousal level increases above that point (the classic inverted U curve). This proposed relationship between arousal and task performance is often attributed to a narrowing of attention that occurs under conditions designed to induce arousal (Easterbrook, 1959). The first inputs to be reduced (dropped out) are those that are irrelevant or only partially relevant to task performance. As arousal increases, attention is further restricted and task relevant cues are also neglected. In some tasks, proficiency demands the use of a wide range of cues (e.g., dual-task performance or single tasks that require the integration of information from many sources). Any narrowing of attention is likely to adversely affect performance of such tasks because remaining attention would likely be less than that required to process task-relevant cues. In other tasks, proficiency demands the use of only a restricted range of cues. Such tasks improve with moderate reductions in attentional span (improvement in performance occurs only to the extent that reducing competing cues facilitates a particular task) but are detrimentally affected

when available attention falls below that required to process task-relevant cues. Thus, continued reduction in attentional span will improve and then impair performance.

It follows that the optimal level of arousal (and thus attentional focus) varies with the complexity (number of cues required) of the task. Optimal levels of arousal for complex tasks are lower than those for simple tasks. Thus high levels of arousal, like those that are presumably elicited by laboratory stress manipulations, are usually assumed to have detrimental effects on complex tasks but not on simple tasks. Assuming that the standard aftereffects measures are complex tasks and that subjects are experiencing a high level of arousal following stressor termination, arousal theory would account for poststimulation deficits in task performance. However, it is unclear whether the standard aftereffects tasks can be considered complex and/or whether they generally show performance deterioration under heightened levels of arousal. For example, existing data show that Stroop performance often improves under arousal-inducing conditions. (See the review in Broadbent, 1971.) This improvement is attributed to an arousal-elicited focusing of attention on appropriate task cues (colors) and to a consequent dropping out of competing cues (words). As an aftereffects task, Stroop performance suffered following exposure to unpredictable and uncontrollable stress. Moreover, the proofreading task could be classified as a simple rather than a complex task, since it involves processing of only a restricted range of cues (cf. Easterbrook, 1959). Thus we might also expect improved performance on proofreading under heightened arousal.

To further confuse the situation, Poulton (1978) has argued that postnoise effects on task performance are due to the level of arousal falling below normal following exposure. If we assume that the standard aftereffects tasks are simple, this approach would similarly provide an explanation for poststimulation effects, since optimal levels of arousal for simple tasks are presumed to be high and any decrease in arousal would cause a decrease in performance.

Insensitivity to social cues can also be ex-

plained by the arousal model if we assume that levels of arousal are increased following exposure to unpredictable, uncontrollable stress. Increases in arousal level are said to be associated with a focusing of attention on cues most relevant to task performance (Easterbrook, 1959; Kahneman, 1973). As suggested in our earlier discussion of Cohen's (1978) attentional model, attentional focusing could lead to an insensitivity to others' needs.

The omnipresent problem in making arousal theory interpretations is the elusiveness of the arousal concept. Although a detailed description of this problem is beyond the scope of this article, it is important to point out that it is unclear how an investigator is to determine a subject's level of arousal. Some argue for behavioral (subjects behave "as they should" when aroused) and self-report measures (cf. Poulton, 1970), and many investigators use physiological measures—usually measures of autonomic response. Unfortunately, behavioral, physiological and self-report measures of arousal do not consistently correlate with one another (cf. Poulton, 1970). Moreover, it is generally accepted that there is no unitary form of physiological arousal (cf. Lacey, 1967) and that individual physiological measures do not correlate with one another. (See the review by Sternbach, 1966.) Nevertheless, many investigations of arousal under stress in laboratory situations use only one or two measures and assume that they reflect a general level of arousal. Thus the first point to be made is that the existing data on the relationship between poststress arousal level and performance are suspect, since we are not sure what arousal is or how it is to be measured and since we are sure that the way it has been measured in the past is inadequate.

Do those exposed to unpredictable and uncontrollable stressors show different levels of physiological arousal than those exposed to predictable and/or controllable stressors after the stressor is removed? There are little existing data on physiological response after exposure is terminated, but there are considerable data on relative levels of arousal at or near the end of the stress session.³ Glass

and Singer (1972) used three phasic measures of arousal in their research: Palmar skin resistance, vasoconstriction of blood vessels in the fingertip, and an electromyographic (muscle tension) measure. They reported that subjects habituate on all three autonomic channels, irrespective of the unpredictability and perceived controllability of the noise. That is, by the end of the exposure period, there is no difference among experimental groups in the levels of reaction to stressor stimuli obtained. A similar lack of differences between conditions in phasic response was reported in two studies of perceived control over the termination of noise by Pennebaker et al. (1977). This lack of differences, however, is inconsistent with some earlier research which suggested that there are significant reductions in electrodermal response, in conditions in which the subject can control or predict the onset and/or offset of stressor stimuli (e.g., Champion, 1950; Corah & Boffa, 1970; Geer, Davison, & Gatchel, 1970).

It is, however, more generally acceptable to use tonic rather than phasic response as a measure of a general level of arousal (cf. Glass & Singer, 1972). The only study that compared tonic response after exposure to predictable or unpredictable noise (Weidner & Matthews, 1978) found that subjects exposed to noise as compared with quiet had

³ The exception to this is evidence that during the initial stage of an anagram test, administered after noise exposure, students exposed to inescapable noise (learned helplessness condition) had a lower skin conductance level (SCL) than did those exposed to escapable noise (Gatchel & Proctor, 1976; Gatchel et al., 1977). An experimental control group in which subjects merely listened to loud tones (equivalent to the Glass and Singer no-control condition) showed the lowest SCL. There were, however, no differences between conditions on skin conductance response in either study. Moreover, the earlier study (Gatchel & Proctor, 1976) found no differences among escape, experimental control, and no-escape (helplessness) conditions following noise for either spontaneous skin conductance fluctuations or heart rate. As suggested earlier, these studies did not find postnoise behavioral aftereffects in the experimental control condition that was similar to the no-perceived-control condition in the Glass and Singer studies.

elevated hand temperature and blood pressure but that subjects exposed to predictable versus unpredictable noise showed no difference. Glass and Singer also reported that there were no differences between various experimental conditions in their studies in the level of skin conductance during stressor exposure, and a later study of control over electric shock (Glass et al., 1973) similarly indicated no difference between conditions in tonic conductance. Some earlier studies, however, suggested that those with control over termination of a stressor do show lower tonic levels during stressor exposure (e.g., Geer et al., 1970), although the evidence is mixed (e.g., Glass et al., 1973; see, also, review by Averill, 1973).

Comparisons of tonic arousal levels under stress and no-stress conditions (no manipulations of control or predictability) have, however, suggested differences at or near the end of the stress session (e.g., Aiello, Epstein, & Karlin, 1975; Evans, 1979), but only mixed support for differences comes from the studies that assessed arousal after the stressor was removed (Frankenhaeuser & Lundberg, 1974; Rotton et al., 1978; Weidner & Matthews, 1978). Thus it appears that there is little evidence for differential levels of physiological response following stressor termination. However, as we have suggested, "the fact that one autonomic measure fails to reveal expected differences does not necessarily rule out the existence of arousal differences" (Glass & Singer, 1972, p. 146).

Self-report measures of stress also provide only meager evidence for differential levels of arousal among the various experimental conditions. Although Glass and Singer (1972) reported a study in which one self-report measure suggested greater stress for those in the unpredictable, uncontrollable stress conditions, as opposed to those exposed to predictable and/or controllable stress (p. 66), for the most part these measures covary with the presence or absence of the stressor but not with the presence or absence of control or predictability. Several later studies (Mills & Krantz, 1979, Experiment 2; Pennebaker et al., 1977) similarly reported no differences between those with and those without control

on self-reports of frustration, tension, and alertness. The previously described study by Sherrod and his colleagues (1977) also found that neither initiation nor termination control affected self-reports of stressfulness.

In sum, there is little evidence for differential levels of arousal following an unpredictable, uncontrollable stressor, as opposed to predictable and/or controllable stressor. Moreover, it is also unclear whether such differences in arousal level would have consistently negative effects on the standard aftereffects tasks.

Frustration-Mood Hypothesis

A simple explanation for the aftereffects of stress is that exposure to unpredictable, uncontrollable stressors causes frustration, annoyance, and irritation, which results in a less motivated performance on poststress tasks and in a lower likelihood of being sensitive to the needs of others. There is evidence that those who experience a negative mood state are less likely to help another (cf. Isen, 1970; Moore, Underwood, & Rosenhan, 1973) and that frustration often results in aggression and other negative interpersonal behaviors (e.g., Berkowitz, 1969). Evidence that those exposed to unpredictable, uncontrollable stressors experience negative mood states following stress termination is, however, equivocal.

The study that comes closest to testing the frustration-mood hypothesis is Donnerstein and Wilson's (1976) investigation of poststress aggression. Consistent with the frustration-mood hypothesis, those subjects who were exposed to noise without perceived control (and thus who were presumably frustrated) and who were also angered (additional frustration) administered more shock to a confederate than either subjects with perceived control over the termination of the noise or those who were not angered. A number of other studies, however, do not indicate any differences in poststress annoyance and irritation between those with and those without perceived control (Glass & Singer, 1972; Pennebaker et al., 1977; Sherrod et al., 1977). Moreover, even studies that compared unpredictable, uncontrollable stressors to no-

stress experimental control conditions often indicated that there were no reliable differences in reported mood between conditions (e.g., Cohen & Spacapan, 1978; Frankenhaeuser & Lundberg, 1974; Wohlwill et al., 1976) and that the overall mood of subjects in all conditions was positive following the experimental session (e.g., Cohen & Spacapan, 1978; Wohlwill et al., 1976). These studies, however, typically include only one or two global items about the "stressfulness" or "enjoyableness" of the experiment and thus may not provide a sensitive measure of mood. As summarized earlier (in the section on Arousal Theory), there is also little evidence for the differential levels of arousal that one might expect to be correlated with increased frustration and mood shifts. In sum, although a frustration-mood hypothesis is compelling because of its simplicity, there are few data which suggest that significant differences in mood or arousal actually exist following the various experimental conditions.

Persistent Coping Strategies

It is possible that those exposed to unpredictable, uncontrollable stressors use coping strategies during stressor exposure and maintain these strategies even after the stressor is terminated. Although a particular strategy may be adjustive during exposure, it may or may not prove to be adaptive after exposure termination. This persistence may be due to overlearning of a coping response (cf. Rodin & Baum, 1978). This approach suggests that the coping response is under stimulus control but is not voluntary. For example, one may cope with crowding by withdrawing and persist in withdrawing from strangers even when not crowded.

The laboratory study of spatial density by Epstein and Karlin (1975) provided evidence for the persistence of a coping strategy that is used during stress exposure. They reported that single-sex groups of women and men differed in their reaction to crowding stress. Consistent with cultural norms, women tended to share their distress with each other, whereas men tended to hide their distress. These norms of sharing and hiding persisted into the poststress session in which men who

had been crowded were less cohesive and more competitive than uncrowded men and in which women who had been crowded were more cohesive and less competitive than uncrowded women. Baum and Valins (1977) studies of dormitory design similarly suggested the persistence of a coping response. Those subjects from dormitories with a high level of forced interaction made more active attempts to avoid the possibility of contact with a stranger outside of the dormitory than those from dormitories with lower levels of interaction. Thus, an avoidance response that presumably developed as an attempt to cope with dormitory life seemed to persist even outside of the dormitory setting.

A persistent coping strategy as a response to prolonged exposure to noise was proposed by Deutsch (1964). She suggested that children reared in a noisy environment eventually become inattentive to acoustic cues; that is, they learn to "tune out" sound. In tuning out his or her noisy environment, a child is not likely to distinguish between speech-relevant and speech-irrelevant sounds. Thus he or she will lack experience with appropriate speech cues and will generally show an inability to recognize relevant sounds and their referents. The inability to discriminate sound is presumed to account, in part, for subsequent problems in learning to read. A child who cannot readily discriminate basic speech sounds faces a difficult task in learning to associate these sounds with their appropriate signs.

A study described earlier by Cohen et al. (1973) found some evidence for this hypothesis by establishing that children who spent their earlier years living in an intensely noisy environment were unable to develop adequate auditory discrimination ability and unable to acquire basic reading skills. There was, however, no direct measure in this study of the tuning out strategy. One strong alternative hypothesis is that the traffic noise made it difficult for the children to hear their parents (speech was masked) and consequently to learn auditory discriminations. A later study by Heft (1979), however, does provide evidence for the use of a tuning out strategy on the part of children living in

noisy environments. If children exposed to noise tune out their acoustic environment, they should be less affected by an auditory distractor than are children from quieter environments. Heft found that the performance of children from homes described by parents as noisy was less strongly affected by the presence of an auditory distractor than was the performance of those from homes described as quiet. Unfortunately, children from noisy homes performed more poorly under quiet conditions than those from quiet homes, which suggests that the lack of a distraction effect might be attributable to a base performance level that could not get much worse under any condition (floor effect).

In sum, evidence from laboratory and naturalistic research suggests that persistent coping strategies are responsible for at least some poststimulation effects. Although the data previously described are limited to situations in which the coping strategy is one that develops as a response to a particular stressor (e.g., withdrawal as a response to crowding), it is possible that general strategies that are used to cope with a wide range of stressors persist after stressor termination (cf. Milgram, 1970). For example, the strategy of focusing one's attention on the essential aspects of a task during exposure (e.g., Hockey, 1970; Wachtel, 1968) may persist even after exposure is terminated. This could account for the decrements in performance on complex tasks reported in the aftereffects literature.

Dissonance and Self-Perception

In their early effort to explain aftereffects, Glass and Singer (1972) alluded to cognitive dissonance (Festinger, 1957) and self-perception analyses (Bem, 1967). Briefly, these analyses suggest that since subjects with perceived control choose to be exposed to the noise for little incentive, they judge it less stressing and therefore do not show aftereffects. However, when Glass and Singer (1972, p. 106) turned to a classical dissonance manipulation—allowing or not allowing subjects to choose whether they would be exposed to noise—they were unable to produce aftereffects on the proofreading or

Stroop tasks. Sherrod et al. (1977), however, reported that allowing subjects to choose whether they would be exposed to noise did partially ameliorate poststimulation deficits in performance. On the other hand, although the choice manipulation in the Glass and Singer study affected a subject's willingness to participate in a future experiment, Sherrod et al. reported that willingness to participate in a future study was unaffected by manipulations of initiation and termination control. Thus the evidence relevant to this hypothesis is at best mixed.

Although these theories provide an explanation for the ameliorative effects of control, they do not explain why poststimulation effects occur in the unpredictable, uncontrollable stressor conditions. Moreover, it is difficult to apply this interpretation to studies in which subjects have control over an aspect of the situation but not directly over the stressor (e.g., choice of hand to be immersed in cold water, Mills & Krantz, 1979) and studies in which the subject actively copes or implements control (e.g., Glass et al., 1973).

Artifacts of the Experimental Situation

Most of the laboratory aftereffects research has been done with both the exposure task and aftereffects tasks conducted in the same laboratory setting and with the same experimenter. One likely explanation for these effects is that subjects exposed to the more aversive stress—that which is unpredictable and uncontrollable—develop a negative attitude about both the experimenter and the experimental setting. Once deciding that he or she does not like either the experimenter or experiments in general, a subject does not work as hard on subsequent tasks. Glass and Singer (1972) attempted to determine the subjects' attitudes about the experimenter by having them fill out an evaluation form following the experimental session. The form was presented in a way that guaranteed the subjects anonymity and suggested that negative evaluations would not be held against the experimenter. Although there were large mean differences (subjects with perceived control liked the experimenter more than

those without control), these differences did not reach statistical significance. Sherrod et al. (1977) also reported no differences between those with and those without control in either liking the experimenter or enjoying the experiment. Later studies that both separated the aftereffects task from the stress situation (e.g., Cohen & Spacapan, 1978; Sherrod & Downs, 1974) and assessed the effects of a naturalistically occurring stressor (e.g., Baum & Valins, 1977; Cohen et al., 1980; Rodin, 1976) are not subject to the artifactual explanation.

Discussion

What Do We Know?

The following is a list of the most striking contributions from the studies reviewed in this article:

1. The poststimulation effects of unpredictable, uncontrollable stress on performance have been replicated in a myriad of different laboratories and with a variety of subject populations. They occur as a consequence of a wide range of stressors including noise, electric shock, density, and cold pressor. Moreover, interventions that increase control and/or predictability are effective in reducing these effects. The bulk of the laboratory work, however, has used a limited number of aftereffects tasks whose common characteristics are not clear.

2. The aftereffects of stress can also be induced by high attentional demands. Thus these effects are not limited to a restricted range of stressful situations that involve a lack of predictability and control over a distracting and/or intense stimulus.

3. There are poststimulation effects on social behavior as well as on performance. These effects generally involve an insensitivity toward others following stress exposure.

4. Poststimulation effects of environmental stressors occur following prolonged exposure in naturalistic settings. These studies generally suggest that these effects are mediated by helplessness. It is, however, unclear whether the mechanisms involved in producing these effects are the same as those responsible for deficits in task performance

and in interpersonal response following short-term exposure.

5. There is increasing evidence that various forms of control have ameliorative effects similar to those of perceived control over the termination of the stressor. These include termination control in which one actually performs a coping response (implemented control) as well as initiation, choice, and information control. Moreover, some evidence suggests that combining more than one mode of control will further improve poststimulation performance. This improvement, however, seems to reach asymptote at the performance level reached by the no-stress control condition.

We have documented a wide range of stress aftereffects. Although it would be parsimonious to suggest that after further investigation of the problem, the mechanism responsible for these effects will be isolated, the assumption of a unitary explanation for such a wide range of behaviors may be unreasonable. It is likely that the reliability and generality of poststimulation effects occurs in part because of a multiplicity of causes. Thus the eventual goal of research in this area should be to determine the specific conditions that elicit each of a number of cognitive or motivational mechanisms and to determine specific kinds of tasks and behaviors affected by each.

The research reviewed in this article does not provide evidence from which to accept or reject the adaptive-cost hypothesis from which this literature was spawned. However, many of the proposed explanations for stressor aftereffects are, in fact, forms of that hypothesis. They suggest that poststimulation effects are either directly or indirectly caused by the process of coping with stress. The mechanisms proposed included cognitive fatigue that results from the coping effort, feelings of helplessness that result from a failure to cope, and the overlearning of a coping response. Thus 10 years of intensive research has led to the recognition of the costs of adapting to stress, and although this work has answered few specific theoretical questions, it has provided us with an appreciation of the impact of the adaptive process.

Environmental Stress and Health

Gary W. Evans
Cornell University

Although environmental conditions play a prominent role in health and psychological processes, antecedent factors in these processes have largely been neglected within health psychology. Instead, the focus has been on various markers of health, with considerable attention to stress-related mechanisms, interceding between the environment and health. Another focus within health psychology that has directed attention away from environmental factors has been coping resources, with the examination of either social support, personality, or coping strategies that potentially alter the impact of environmental demands on health. But what characteristics of the environment itself are likely to impinge on health and psychological processes? When this question has been addressed within health psychology, environment has been operationalized primarily in social terms. Family and work social climates, as well as sociocultural and economic conditions, predominate in the few environmental studies in health psychology. This chapter intends to draw greater attention to the potential role of the physical environment in health and psychological processes.

Why might the physical environment be important to health psychology? For one reason, the physical environment clearly impacts health. Adverse physical conditions can cause toxicological reactions, challenge homeostatic balance, produce physical trauma, or function as vectors bearing pathogens. Physical factors can also be a source of environmental demands that pressure coping resources.

A second reason the physical environment is worthy of scrutiny within health psychology is because the environment can be modified and thus becomes a potential intervention target to improve health and well-being. Third, environmental conditions are objective and thus can be measured more readily

in reliable and valid ways. For example, researchers can systematically monitor density or noise levels in precise, accurate ways that can then be examined as possible causal factors in health. Fourth, physical environmental conditions tend to be stable. Increasingly, research suggests that chronic environmental demands are most likely to have negative impacts on health (Lepore, 1995). Finally, the concept of psychological stress that is central to several formulations of health, behavior, and disease (see chap. 17, this volume) has been utilized to broaden understanding of how physical features of the environment can influence human health and well-being.

There are at least three major ways in which the physical environment might operate as a psychological stressor, straining human adaptive capacities. First, this can occur when a stressor directly loads, or pressures, the system. Both crowding and noise, for example, create a surfeit of stimulation that can directly overload the system, causing discomfort, negative affect, and under some circumstances, the marshaling of adaptive resources. Both negative affect and adaptive responses to challenge or threat in turn directly affect neuroendocrine and cardiovascular functioning. Physical stressors can also interact with psychosocial conditions to exacerbate negative affect and/or psychophysiological mobilization. For example, noise plus high workload demands leads to more serious health outcomes than workload levels alone. Noise and crowding frequently covary with other psychosocial risk factors (e.g., poverty, inadequate working conditions), and thus have the potential to contribute to multiple risk situations.

A second manner in which the physical environment can contribute to stress is by damaging or ameliorating coping resources themselves. People rarely respond to suboptimal physical or psychosocial conditions passively; instead, they

invoke various coping strategies to reestablish some modicum of balance between environmental demands and personal resources. Evidence is presented herein, for example, that crowding interferes with the development and maintenance of socially supportive relationships in the residential environment. Both chronic noise and chronic crowding appear to contribute to learned helplessness, adversely affecting self-efficacy and related motivational processes.

The third way in which physical conditions can operate as stressors is to elicit coping strategies that in turn lead to poor health. Studies of noise, for example, reveal that increases in substance abuse occur under noisy working conditions.

Another aspect of research on psychological stress and health relevant to this chapter on environmental stressors are the concepts of vulnerability and resilience (Cohen, Kessler, & Gordon, 1995; Rutter, 1983). Just as certain personal or situational characteristics can render individuals more or less vulnerable to social stressors, there is evidence of vulnerable subgroups among the population who appear more adversely affected by noise and by crowding, respectively. Thus throughout both direct, main effects and associations between environmental stressors and health, as well as occasions with vulnerable subgroups, are noted.

The field of environmental stress (Cohen, Evans, Stokols, & Krantz, 1986; Evans, 1982; Evans & Cohen, 1987) is sufficiently developed such that exhaustive coverage is impossible. A small amount of environmental stress research has examined climatic conditions as potential psychological stressors influencing human stress responses (Bell & Greene, 1982; Evans, 1994). Research on housing conditions as a possible stressor have also been undertaken (Freeman, 1984). The focus of this chapter is on the two most studied environmental stressors, crowding and noise. Health outcomes include physical health and psychological health. Moreover, the chapter examines underlying psychosocial and psychophysiological processes that may help explain the linkages between noise and crowding and major physical and psychological health outcomes. Psychophysiological mechanisms, immune function, social resources, coping strategies, and motivational processes are examined.

CROWDING

The element of crowding that relates most strongly to physical and psychological health is people per room. Traffic congestion may also prove to be a potent stressor. Area measures of crowding, such as people per acre, generally have little or no relation to health. Although some studies of crowding separate group size effects from density effects, the vast majority of studies have confounded these two factors, manipulating or measuring density as it covaries with group size. Therefore, some of the effects attributed to crowding may be due to group size rather than the amount of space per person. At the same time, when attempts have been made to distinguish between these related concepts, density and group size, the impacts of density typically persist.

Physical Health

Early interest in crowding in the public health field emanated from concerns about the spread of disease among crowded populations (Cox, Paulus, McCain, & Karlovac, 1982). There is a large literature on this topic. Physical health has been operationalized in this literature as rates of illness based on archival data, visits to infirmary, physical development among children, and self-reports of somatic symptoms. Archival evidence for positive associations between crowding and ill health come from studies in prisons (McCain, Cox, & Paulus, 1976; Paulus, 1988), refugee camps (Arnow, Hierholzer, Higbee, & Harris, 1977), and schools (Essen, Fogelman, & Head, 1978; Koopman, 1978). The Arnow et al. (1977) study is noteworthy because they demonstrated good correlation over time between Vietnamese refugee camp population fluctuations with changes in a highly contagious disease (acute conjunctivitis). There is also evidence that crowded residential conditions are linked to disease both among children (Booth & Johnson, 1975; Jacobson, Chester, & Fraser, 1977) and among adults (Levy & Herzog, 1978; McGlashen, 1977; Menton & Meyers, 1977; Sims, Downham, McQuillin, & Gardner, 1976; Wyndham, Gonin, & Reid, 1978; Yarnell, 1979). Yodfat, Fidel, Cohen, and Eliakim (1979) found that linkages among residential crowding and asthma were due to number of children rather than density per se. Booth (1976) found that male adults, but not women, had greater levels of disease in crowded homes. Traffic congestion levels among commuters is also associated with illness-related absenteeism from work (Novaco, Stokols, & Milanesi, 1990).

Several studies of residential crowding find little or no correlates with disease (Brett & Benjamin, 1957; Collette & Webb, 1974; Mackintosh, 1934; McKinlay & Truelove, 1947; Quinn, Lowry, & Zwaag, 1978), and Winsborough (1965) uncovered an inverse relation between areal density and tuberculosis. Schmitt and colleagues also found no relation between residential density and disease rates, but found small, positive correlations with areal density (people per acre) measures (Schmitt, 1966; Schmitt, Zane, & Nishi, 1978). Similar trends have been uncovered by Levy and Herzog (1974). Kellett (1984) made the important point that certain diseases should be expected a priori to correlate with crowding more so than others. Kellett examined mortality patterns for specific diseases in London for a 5-year period. As in prior work, persons per room rather than people per acre appeared more useful in predicting mortality. Second, diseases wherein a major stress component is believed to be operative (e.g., hypertension, myocardial infarction, vascular disorders, asthma) were related to household crowding whereas many other diseases (e.g., various forms of cancer) were not.

Freedman and colleagues challenged many of these studies of crowding and disease, noting that poor or nonexistent controls for other variables such as socioeconomic status are common in the crowding and epidemiological literature. They found in a well-controlled epidemiological analysis that residential crowding was not a significant predictor of disease (Freedman, Heshka, & Levy, 1975). However, the prison

studies and a few of the residential studies (e.g., Menton & Meyers, 1977) do have good controls for SES. Furthermore, there are trends in the data indicating that when individual levels of exposure to density and individual indices of health are compared rather than aggregated population statistics, such as used by Freedman and colleagues, stronger results occur. Nonetheless, Freedman and colleagues' cautious perspective on crowding and disease is well taken. Overall findings are suggestive but not rigorously or consistently supportive of a crowding-disease link. It would be useful to include, in the same individual-based study, disease rates for disorders that ought to vary with stress exposure plus inclusion of immunological measures.

A handful of studies in institutional contexts have examined crowding and infirmary visits. These studies converge on positive associations between levels of crowding and infirmary visits among shipboard military personnel (Dean, Pugh, & Gunderson, 1975, 1978), college campus residents (Baron, Mandel, Adams, & Griffen, 1976; Stokols, Ohlig, & Resnik, 1978), and prisoners (Paulus, 1988). The prison effects were most noticeable among inmates forced to live under dormitory-like conditions rather than in single cells. Trends also indicated that the associations in prisons were somewhat stronger for men than women and for African American in comparison to Anglo prisoners (Paulus, 1988). Wener and Keys (1988) found that increases in density (doubling up cell mates) markedly elevated (nearly 50%) sick call rates among prison inmates.

A few studies have examined physical development among crowded children, uncovering evidence of negative associations between household density and physical stature (Booth, 1976; Essen et al., 1978; Goduka, Poole, & Aotaki-Phenice, 1992). Crowded children, particularly boys, are shorter. Shapiro (1974) also found that boys, but not girls, motoric development appeared to be inhibited in crowded homes. Moreover, this effect was amplified among children of less educated mothers. More recently, Widmayer and colleagues (1990) found delayed psychomotor development among infants as a function of household density, controlling for socioeconomic status (SES).

Self-reported levels of physical illness are positively associated with crowding in prisons (Cox, Paulus, & McCain, 1984; McCain et al., 1976), among college dormitory women but not men (Karlin, Epstein, & Aiello, 1978), and among crowded home settings (Gove & Hughes, 1983)—although Booth (1976) found this association among men, but not women, in crowded homes. Giel and Ormel (1977) and Baldassare (1979) failed to replicate the association between home crowding levels and self-reported illness. The validity of all the self-report data on illness and crowding is suspect given retrospective self-report indices. On the other hand, Cox et al. (1984) found a dose-response function between number of inmates per cell and self-reported illness levels among male prisoners. Of additional interest, Gove and Hughes (1983) provided some evidence that heightened illness levels associated with crowded residences are related to lack of sleep and lower resistance when exposed to other sick family members (all self-reported).

There is evidence that some of the association between crowded living conditions and self-reported health symptoms is mediated by loss of perceived control over the living environment. Ruback and associates found that both female and male prisoners' reports of ill health in association with crowding were also negatively related to perceived control (Ruback & Carr, 1984; Ruback, Carr, & Hopper, 1986). Another way in which environmental stressors like crowding can impinge on health is through injuries. Rhesus monkeys when crowded for example, show a 5-fold increase in incidents of injury (Boyce, O'Neill-Wagner, Price, Haines, & Suomi, 1998).

Psychophysiological

Several studies have examined the relation between crowding and blood pressure in people. Laboratory studies with random assignment to density levels have found small but significant elevations among crowded versus uncrowded participants (Epstein, Lehrer, & Woolfolk, 1978; Evans, 1979). Field studies of prisoners (D'Atri, 1975; Paulus, McCain, & Cox, 1978) and automobile commuters (Novaco, D. Stokols, Campbell, & J. Stokols, 1979; Schaeffer, Street, Singer, & Baum, 1987; Stokols et al., 1978) have also revealed correlational evidence for elevated blood pressure under more crowded or congested living or commuting conditions. The commuting studies have found that the effects are stronger for car poolers rather than solo drivers, for Type B rather than Type A drivers, among external versus internal locus of control drivers, and among drivers with less residential choice. One field study found no relations between chronic residential crowding and blood pressure or neuroendocrine indices among adults (Booth, 1976), although small, statistically significant elevations in serum cholesterol were noted among crowded men. No such correlation was noted among women. Booth's sample did not vary much in density, which may have weakened his findings. Evans, Lepore, Shejwal, and Palsane (1998) found elevated blood pressure among crowded boys, but not girls, among working-class families in India.

Another cardiovascular function, blood pressure reactivity, has been related to chronic crowding in adults. Residents of more crowded neighborhoods had higher reactivity (increase from baseline in blood pressure levels) and took longer to return to resting baseline levels (Fleming, Baum, Davidson, Rectanus, & McArdle, 1987). Both heightened reactivity and protracted recovery to baseline are potentially important precursors to the development of coronary heart disease.

Neuroendocrine markers of stress, typically urinary catecholamines and cortisol, have been noted in several studies of crowded commuters (Lundberg, 1976; Singer, Lundberg & Frankenhaeuser, 1978) and among bus drivers operating under more congested driving conditions (Evans & Carrere, 1991).

Pedestrian exposure to more crowded urban areas elevates neuroendocrine activity, at least for males (Heshka & Pylypuk, 1975), and residence in neighborhoods perceived as more crowded because of commercial establishments and more people on the street is associated with increased urinary catecholamine levels (Fleming, Baum, & Weiss, 1987). Dor-

itory crowding, however, had no apparent effects on neuroendocrine activity among college students (Karlin et al., 1978). A small sample size may have rendered low power. These authors did find, however, that uncrowded residents' neuroendocrine indices dropped over the course of the semester, whereas crowded residents' neuroendocrine levels increased over the same time period. Schaeffer, Baum, Paulus, and Gaes (1988) found that prisoners housed in more open, unpartitioned dormitories felt more crowded and experienced elevated chronic catecholamine levels in comparison to prisoners living in smaller groups.

The critical role of control has been implicated in some of these psychophysiological crowding studies. Lundberg (1976) and his colleagues found that passengers with greater choice over seating were less negatively impacted by congested commuting. Evans and Carrere (1991) found that the neuroendocrine effects of traffic congestion on bus drivers were largely mediated by perceived control on the job. On the other hand, perceived control did not mediate the positive relation between prison crowding and neuroendocrine elevations (Schaeffer, Baum, Paulus, & Gaes, 1988).

A few laboratory studies have also utilized skin conductance as an index of psychophysiological stress, generally finding elevations among more crowded participants (Aiello, Epstein, & Kalin, 1975; Aiello, Nicosia, & Thompson, 1979; Bergman, 1971; Nicosia, Hyman, Karlin, Epstein, & Aiello, 1979). Studies of crowding and skin conductance are evenly split on gender differences, with some studies finding more pronounced effects among males than females and other studies finding no sex differences. There is also evidence that skin conductance may be more strongly affected by crowding when physical touching occurs. McCallum, Rusbult, Hong, Walden, and Schopler (1979) found that acute crowding elevated palmar sweat but only when experimental subjects were motivated to maintain high levels of group performance. When performance was permitted to deteriorate under crowding, no physiological elevations were noted. Finally, in a field study, Cox, Paulus, McCain, and Schkade (1979) found a significant positive correlation between the palmar sweat index and crowding among prison inmates.

Although indirect, some findings by Hutt and Vaizey (1966) may shed some light on psychophysiological mechanisms associated with crowding and psychophysiological responses. Chronically overaroused children responded to high density laboratory conditions by extreme social and physical withdrawal; whereas chronically underaroused children and children without arousal disturbance reacted in the opposite direction, becoming more engaged and aggressive with other children.

Many animal studies have examined endocrine activity among crowded species both under laboratory and field conditions (see Evans, 1978, for a review). Generally, this research indicates support for a population regulation feedback mechanism whereby crowded animals' fertility declines. This occurs more markedly among subordinate rather than dominant animals and appears to be mediated by adrenal cortical activity. Attempts to link crowding with population regulation among human beings have proven futile.

Immune Function

Animal but not human work has examined immunological processes as a function of crowding, generally finding evidence of compromised immune functioning among more crowded animals (Christian, 1963; E. A. Edwards & Dean, 1977; Thiessen & Rodgers, 1961). These effects appear to be stronger among subordinate rather than dominant animals and among animals without a history of crowded living conditions (Cassel, 1971). Cassel (1974) pointed out, however, that compromised immune function alone cannot account for changes in morbidity among crowded animals because both infectious and noninfectious diseases are elevated among crowded animals.

Psychological Health

Ever since 1962 when Calhoun published his famous *Scientific American* study of pathology among overpopulated rats, researchers and policymakers alike have wondered about the potential role of crowded living conditions on mental health. The chapter first reviews research on linkages between density and psychological distress and then turns its attention to recent work examining possible underlying mechanisms for this linkage.

Many studies have uncovered positive relations between residential density and self-reported psychological distress (Edwards, Fuller, Sermisri, & Vorakitphokatorn, 1990; Evans, Palsane, Lepore, & Martin, 1989; Gabe & Williams, 1987; Gove & Hughes, 1983; Hassen, 1977; Jain, 1987; Lakey, 1989; Marsella, Escudero, & Gordon, 1970). Mitchell (1971) found greater worrying among crowded families but only if they were also poor. Crowding in Mitchell's study was unrelated, however, to more serious indices of psychiatric illness. Lepore, Evans, and Schneider (1991) found evidence that residential crowding causes psychological distress in a prospective, longitudinal study of crowding and mental health. Controlling for educational levels and income, they found that crowded residents did not differ from uncrowded residents in psychological distress symptoms during initial occupancy ($r = .12$), but after 2 months and 8 months the associations became significant ($r = .21$; $r = .27$). This is the only prospective study of crowding and health. Webb and Collette (1975) found an association between residential density and use of prescription hypnotics.

Booth (1976), Baldassare (1979), and Giel and Ormel (1977) failed to find a positive association between residential crowding and psychological distress. These studies had little variance in density. Moreover, Baldassare relied on mental health indices of questionable sensitivity (one dichotomous item in one case, and three dichotomous items in a second case). Two studies of neighborhood crowding levels have also found linkages to psychological distress (Collette & Webb, 1974; Fleming, Baum, & Weiss, 1987).

Studies utilizing archival indices such as psychiatric admissions or suicide rates generally find very weak or insignificant associations between crowding and pathology when measured in the aggregate (Freedman et al., 1975; Gove &

Hughes, 1980; Schmitt, 1966; Schmitt et al., 1978). In some studies negative associations between density and psychiatric admissions have been uncovered, probably created by the association of living alone and mental disorder (Galle, Gove, & McPherson, 1972; Levy & Herzog, 1974, 1978). One exception to these generally negative trends in archival indices of mental health and crowding is notable. Several prison studies have found clear, strong associations between the total population size of prison populations and indices of psychiatric illness (Paulus, 1988).

Quite a number of studies have examined psychological symptoms among children living in crowded homes. Plant (1937) described several case studies noting a pattern of low self-sufficiency and little idealism among children from crowded homes. He attributed these patterns to mental strain associated from always having to get along with others and to exposure to adults under close quarters that made it difficult to look up to or idealize grownups. Crowded children have increased levels of various symptoms of psychological distress (Booth, 1976; Gasparini, 1973; Murray, 1974; Saegert, 1982; Wachs, 1987). Parents in more crowded homes report relief when their children are outside (Gove & Hughes, 1983), have more difficulty supervising their children (Mitchell, 1971), and are generally less responsive and involved with their children (Bradley & Caldwell, 1984; Evans, Maxwell, & Hart, 1999; Wachs & Camli, 1991) in comparison to uncrowded parents of comparable social class. These trends appear to be exacerbated in the presence of other risk factors, particularly poverty (Baldassare, 1981; Bradley et al., 1994).

Psychosocial Resources

Some of the relation between high residential density and psychological distress in children may be linked to family interactions, which have been found to be more contentious under crowded living conditions (Booth, 1976; Gasparini, 1973; Saegert, 1982). There may also be greater incidence of physical punishment and open expression of anger between parents and children in crowded homes (Booth & Edwards, 1976; Light, 1973), although Gove and Hughes' (1983) study did not support this finding.

Another factor that may help explain the link between high residential crowding and symptoms of psychological distress in children is withdrawal. Aiello, Thompson, and Baum (1985) reviewed several field and laboratory studies documenting increased social withdrawal under crowded conditions among young children. Similar trends exist in the adult literature, indicating that crowded adults interact with housemates less (Baum & Valins, 1977, 1979; Proshansky, Ittelson, & Rivlin, 1970); are less friendly with their neighbors (McCarthy & Saegert, 1978), and have impaired social support with those they live with (Evans et al., 1989; Lakey, 1989; Lepore et al., 1991). Baldassare (1979) did not replicate linkages between residential crowding and neighboring. People under crowded conditions also tend to be less affiliative in their behaviors toward others (R. L. Munroe & R. H. Munroe, 1972) and view others in more negative or suspicious terms (Bickman et al., 1973; Griffitt & Veitch, 1971; McCarthy &

Saegert, 1978). There is also evidence that crowded working conditions lead to greater social withdrawal from coworkers (Oldham & Fried, 1987). Finally, as already noted, parents in crowded homes are less responsive to their children (Bradley & Caldwell, 1984; Wachs & Camli, 1991). Furthermore, this relative unresponsiveness partially accounts for less complex parent to child verbalizations to infants and toddlers (Evans, et al., 1999).

Evidence that social withdrawal and impaired social relationships are a primary mechanism accounting for the relation between crowding and psychological distress has been documented in some detail by two research programs. Baum and colleagues found that more crowded dorm residents report more unwanted social interaction in their dorms. These same crowded residents also evidence greater behavioral indices of withdrawal outside of the dorm. They sit farther away from other research participants and withdraw more in group interaction games (Baum & Valins, 1977, 1979). Residential exposure to high levels of street traffic is also associated with less neighboring (Appleyard & Lintell, 1972; Halpern, 1995). Evans and Lepore showed direct evidence for a similar pattern. They found both cross-sectionally (Evans et al., 1989) and in a prospective, longitudinal design (Lepore et al., 1991) that the negative effects of residential crowding on psychological distress (with controls for social class) are mediated by social support. Similar patterns also appear to occur among children in crowded residences (Evans, et al., 1998).

Evans and Lepore (1993a) also found that crowded relative to uncrowded residents were less likely to offer support to a confederate under stress in an uncrowded laboratory setting. Of additional interest, crowded residents in comparison to uncrowded residents were also less responsive to offers of social support during a stressful situation (see Fig. 20.1). *Ignored* meant that the subject did not look at or made no verbal acknowledgment of the confederate; *acknowledgment* meant some brief comment or a head nod was given in response to offers of support; and *accepted* meant the subject was very re-

FIG. 20.1

sponsive to the confederate's offers of support, elaborating or embellishing on their offers of support.

Motivation

Many theorists have postulated that a prime reason why crowding can have negative impacts on psychological health is because of reduced behavioral options and greater difficulty in regulating social interaction (Altman, 1975; Baron & Rodin, 1978; Schmidt & Keating, 1979). An important psychological consequence of prolonged exposure to an aversive, uncontrollable stressor, such as crowding, may be learned helplessness. Persons chronically exposed to crowding report feeling a greater sense of powerlessness over their living environments than their less crowded counterparts (Baum & Valins, 1977, 1979; Baron et al., 1976; Carr, Hopper & Ruback, 1986; Saegert, 1978). Sherrod (1976), Aiello, DeRisi, Epstein, and Karlin (1977), Evans (1979), Nicosia et al. (1979), and Dooley (1978) all found negative aftereffects immediately following laboratory exposure to crowded conditions. Sherrod, Evans, and Nicosia and colleagues each utilized the Glass and Singer (1972) aftereffects paradigm that measures persistence on challenging puzzles. Giving up sooner in the face of challenge in an achievement context may be indicative of greater helplessness (Cohen, 1980; Glass & Singer, 1972). Dooley (1978) incorporated proofreading performance as her aftereffects measure. Saegert, Mackintosh, and West (1975) reported that crowded train stations produced negative aftereffects in women only. Nicosia's data also indicated more severe aftereffects of crowding among women.

Parallel trends to the laboratory work have been noted in studies of more chronic, crowded living conditions, finding less persistence on difficult puzzles among persons living in more crowded neighborhoods (Fleming, Baum, & Weiss, 1987). Moreover, perception of control over social interactions largely accounted for the main effect of neighborhood crowding on the helplessness indicator. Residents of crowded dorms feel less control over social interaction than their uncrowded counterparts (Baum & Valins, 1977, 1979) and exhibit behavioral strategies in a group prisoners' dilemma game consistent with helplessness (Baum, Aiello, & Calesnick, 1978; Baum, Gatchel, Aiello, & Thompson, 1981). Interestingly, the development of helplessness strategies in the game over the course of the initial semester under crowded conditions was mirrored by residents growing external attributions for problems in the dormitory over this same time period (Baum et al., 1981). Uncrowded residents generally felt self-efficacy over problems in their dormitory over the course of the semester and these internal attributions remained stable over time. Crowded dormitory residents are also less likely to seek clarification when given ambiguous instructions about an impending laboratory procedure than were uncrowded dormitory residents.

Traffic congestion also is related to motivational deficits. Greater traffic congestion levels have been related to decreased task motivation on challenging puzzles and proofreading (Novaco et al., 1979; Schaeffer et al., 1988; D. Stokols, et al., 1978).

The most direct evidence for helplessness induced by crowding comes from a pair of studies on residential crowding and children by Rodin (1976). Matched on socioeconomic indicators, elementary-aged schoolchildren living in more crowded public housing were less likely to control the administration of outcomes in an operant conditioning paradigm in comparison to their less crowded counterparts. In a second study, helplessness was induced in adolescents by a classic helplessness paradigm, pretreatment with an insoluble versus a soluble puzzle. Helplessness was monitored on a second challenging but solvable puzzle. The main effect of pretreatment solvability (the helplessness induction) was significantly moderated by residential crowding with heightened vulnerability to the induction of helplessness among the more crowded children. In their study of children in India, Evans, et al., (1998) replicated Rodin's effects (but for girls only). Saegert (1982), however, did not replicate these findings examining a sample of children from public housing projects in New York City.

Summary

Residential crowding has little impact on physical morbidity among the general population. Residential crowding may be linked, however, to ill health among vulnerable subgroups of the populations, particularly young children and extremely crowded, captive populations (e.g., prisons, refugee camps). Evidence linking high density exposure either under controlled conditions or in the field to elevated cardiovascular functioning is quite strong. Neuroendocrine functioning also appears elevated, although less data are available. The potential clinical implications of these two data patterns has not been explored in the crowding literature.

Psychological distress is increased by residential crowding. Individual but not aggregate level analyses continue to uncover a positive association between crowded living conditions and poorer psychological health. Several studies have excellent controls for sociodemographic factors and one is a prospective, longitudinal analysis. Psychological distress associated with residential crowding may be caused by a typical coping strategy for dealing with chronic high density living conditions—social withdrawal. An unintended consequence of this social withdrawal may be a breakdown in socially supportive relationships. There is not strong evidence, however, that human crowding is associated with more extreme forms of psychopathology characterized in some animal studies as a behavioral sink.

There is also evidence that crowding may lead to the development of motivational deficits, particularly among children in achievement-related contexts. There is indirect evidence suggesting that these motivational deficits are related to learned helplessness from diminished perceived control over the environment.

NOISE

Noise, which is defined as unwanted sound, is typically measured in decibels. Decibels is a logarithmic scale with a

change in 10 decibels perceived as approximately twice as loud. There is considerably more research on noise and health in comparison to research on crowding and health. The bulk of the noise and health research has occurred in industrial settings. More recently, studies of noise and health have also focused on people living in airport impact zones or near to road traffic noise. Prolonged exposure to high levels of noise is clearly linked to hearing damage (Kryter, 1994). Because the thrust of this chapter is on environmental stress, the noise-related hearing damage literature is not discussed.

Physical Health

Studies have examined exposure to either occupational noise or community noise and disease. Outside of cardiovascular problems, there appears to be little relation between noise exposure and physical disease. In industrial settings, noise has been associated with increased risk for myocardial infarction (Ising, Babisch, & Günther, 1999), reductions in cardiorespiratory efficiency (Semczuk & Gorny, 1971), difficulties in peripheral circulation and cardiac problems generally (Jansen, 1961), electrocardiogram abnormalities suggestive of coronary heart disease (Cuesdan et al., 1977), general sickness-related absenteeism (Cohen, 1973), and self-reported fatigue (Carlestam, Karlsson & Levi, 1973; Melamed & Bruhis, 1996). Several industrial studies have found no associations between occupational noise exposure and rates of coronary heart disease (Lees, Romeril, & Wetherall, 1980) or rates of total illness (Lees et al., 1980).

Community airport noise studies have shown that higher levels of noise exposure are associated with greater contact with physicians for coronary-related problems (Knipschild, 1977a) and, for women only, use of drugs to treat hypertension (Knipschild & Oudshoorn, 1977; Koszarny, Maziarka, & Szata, 1981). These studies also show an association with greater physician contact in general (Knipschild, 1977b), rates of colds (Ising et al., 1990), as well as total health symptoms (Pulles & Stewart, 1990), and higher levels of coronary heart disease symptoms among women but not men (Koszarny et al., 1981). Graeven (1974) and Hiramatsu, Tamamoto, Taira, Ito, and Nakasone (1993), however, found no differences in self-reported health symptoms between persons living in airport impact zones versus citizens in quiet neighborhoods.

Turning to road traffic noise, Cameron, Robertson, and Zaks (1972) found little relation between community noise levels (self-reported) and illness rates. Babisch, Elwood, Ising, and Kruppa (1993) found slight elevated risk (1.2 odds ratio) in noisier traffic areas in three different sites for men residing in areas above 65 dBA Leq. However, when comparing across different noise levels varying from > 50 dBA Leq to 70, they uncovered no linear relation.

Another area of physical health worthy of note in the noise literature is birth defects and other abnormalities during pregnancy. Not surprisingly, findings in this area are highly controversial and not at all definitive. Jones and Tauscher (1978) found higher rates of birth defects in high airport noise impact zones relative to quieter areas, but Edmonds, Layde, and

Erickson (1979) could not replicate the findings. Several rodent studies have found abnormal fetal development following noise exposure (Welch, 1973). There is evidence that women working under very noisy conditions, particularly if subjected to additional stressors like shiftwork, have more pregnancy complications such as vaginal bleeding and pregnancy-induced hypertension (Nurminen & Kurppa, 1989). Babies born in areas with high noise impact have lower birth weights (Ando & Hattori, 1977; Knipschild et al. (1981) with controls for socioeconomic status. Ando (1987) also found an increase in low birth weight babies following the opening of a new airport. Schell (1981) also noted that female infants, but not males, had significantly shorter gestation periods in high airport noise impact zones. Moreover, Ando and Hattori (1977) showed diminished levels of human placental lactogen levels in mothers living in high noise airport impact zones. Finally, Schell and Ando (1991) found a dose-response function relating airport noise levels and 3-year-olds' physical stature (but not weight) in a large epidemiological study. The data on possible linkages between noise and early development are sobering to consider in light of environmental surveys of neonatal, intensive care units that are often populated by premature babies. Levels of noise match or exceed recommended standards for ambient traffic exposure and health (Lawson, Daum, & Turkewitz, 1977).

Psychophysiological

Although previous reviews of noise indicate that cardiovascular responses (typically blood pressure or pulse) to noise under acute exposures rapidly habituate (Glass & Singer, 1972; Kryter, 1994), more careful scrutiny of this literature indicates important exceptions. Persons who are noise sensitive do not easily habituate (Conrad, 1973; Stansfeld & Shine, 1993), nor do individuals who are hypertensive (von Eiff, Friedrich, & Neus, 1982). Short-term habituation is blocked when people perform demanding cognitive tasks under noise (Carter & Beh, 1989; Conrad, 1973; Mosskov & Ettema, 1977). Evans et al. (1996) also showed that noise significantly increases blood pressure over a 20-minute period without habituation, if it follows exposure to a psychological stressor (i.e., giving a speech, taking a final examination).

Other psychophysiological indices examined under acute noise have included electrodermal activity, ECG, EEG, and neuroendocrine activity. Results parallel the cardiovascular data, indicating rapid habituation (Finkle & Poppen, 1948; Fruhstorfer & Hensel, 1980). Recent findings suggest, however, that when short-term exposure to loud noise is accompanied by demanding tasks, habituation may be blocked (Frankenhaeuser & Lundberg, 1977; Ising, Rebentisch, Poustka, & Curio, 1990; Lundberg & Frankenhaeuser, 1978). Work by Tafalla and Evans (1997) indicated a central role of effort in the performance/physiological activation tradeoff. Performance can be maintained, at least under many circumstances (e.g., short-term tasks that do not demand large amounts of attention or memory), by additional cognitive effort. Such maintenance of performance, however, appears to exact a cost of greater psychophysiological

activation. It is noteworthy that McCallum et al. (1979) found a very similar pattern for performance under crowded laboratory conditions.

There is also evidence indicating that habituation is interfered with by calling attention to the potential negative impacts of noise on the person (Vera, Vila, & Godoy, 1992). This latter finding might explain why noise sensitive persons apparently do not readily habituate to repeated exposures of acute noise in the laboratory. Perhaps they are more threatened or concerned about potential harmful effects of the noise.

Field research on noise and psychophysiological outcomes has occurred primarily in industrial settings. The occupational noise and psychophysiological literature is too large to review exhaustively herein. Several reviews of this literature (Kryter, 1994; Thompson, 1981, 1993; Welch, 1979) have characterized the findings similarly. Unfortunately, non-experimental designs have frequently been employed in the occupational noise and health literature with poor or nonexistent controls, and many studies have relied on poor estimates of noise exposure. Furthermore, blood pressure is often poorly measured. Many of the industrial studies have relied on one or two measures of blood pressure taken during a physical at work by medical personnel. Moreover, annual medical examinations or other medical screenings may seriously bias estimates since some workers become excluded.

Thompson concluded from her two reviews that workers with adequate hearing protection are unlikely to show much effect of noise on the cardiovascular system. Kryter (1994) reflected greater concern but also remained skeptical, noting the paucity of well-designed research studies; Welch (1979) sounded a considerably greater sense of alarm about cardiovascular health risks from chronic, occupational exposure to noise. Interestingly, Welch's review is based primarily on Eastern European literature that includes worksites with generally very high levels of occupational noise exposure, often coupled with a paucity of hearing protection programs. The bulk of the literature in the other major reviews is based on North American and Western European studies where occupational noise levels tend to be lower and hearing protection programs more common.

Difficulties in exposure estimation in industrial studies of noise and cardiovascular functioning are illustrated by one of the most thorough investigations (Talbot et al., 1985). Although these investigators found no significant differences in blood pressure readings that were carefully administered to men from noisy and from quiet manufacturing plants, they also uncovered a clear, consistent positive link between elevated diastolic blood pressure and severe hearing loss in the noisy plant. Moreover, looking at the subset of men who had worked for at least 15 years in the two respective manufacturing plants, occupational noise exposure did significantly relate to both systolic and diastolic blood pressure (Talbot et al., 1990). See Lercher (1996) for an in-depth discussion of noise exposure estimation and health outcomes.

It is also conceivable that subsets of workers may be particularly vulnerable to the chronic effects of noise exposure on their cardiovascular systems. For example, Tarter and Robins (1990) found that male, African American automobile plant

workers suffered increased blood pressure, whereas their Anglo counterparts, who were exposed to comparable levels of high noise at work, did not show this relation. Tarter and Robins speculated that perhaps racial differences in propensity for hypertension might explain these findings. Given the fact that individual differences in noise sensitivity interfere with habituation to acute noise exposure as reviewed earlier, it might be hypothesized that noise sensitivity creates vulnerable subgroups within occupationally noise-exposed groups. This idea has not been tested, although mixed support of such a pattern has been uncovered in community studies of aircraft noise (Neus, Ruddle, & Schulte, 1983; Stansfeld, 1993).

A few longitudinal studies of noise and cardiovascular functioning in industrial settings have been conducted. By comparing the same worker in quiet and noisy periods, some of the weaknesses most endemic to cross-sectional studies (e.g., selection bias) are reduced. The U.S. Raytheon (1975) study, for example, found a significant reduction in medical problems after the implementation of a hearing conservation program in the plant. No changes in similar health indices occurred over the same time period among workers in quiet plant areas. Moreover, the greater the level of compliance observed (e.g., wearing hearing protection), the greater the apparent health benefit. Hypertension and cardiovascular disease were included in the overall health records monitored but could not be singled out because of insufficient sample size. Antonova (1971) compared miners before and after their workshifts in either noisy or quiet areas of the mine. Noise significantly elevated mean arterial pressure with no changes in the quiet group pre and post work. Systolic blood pressure was significantly elevated among brewery workers when they did not wear ear plugs in comparison to days in which they did (Ising & Melchert, 1980). Cortisol fluctuations were also shown to be dependent on the use of earplugs in a similar design (Melamed & Bruhis, 1996).

Another more rigorous approach to studying industrial noise exposure and psychophysiological responses is to simulate occupational noise exposure under experimental conditions with random assignment to noise conditions. Three-hour exposure to jet turbines significantly elevated blood pressure over resting levels among workers in a jet assembly plant (Ortiz, Arguelles, Crespín, Sposari, & Villafane, 1974). Mosskov and Ettema (1977) and Rovekamp (1983) found elevations in blood pressure in 2- to 3-hour noise exposures but at much lower intensities of noise than employed by Ortiz and colleagues. Cartwright and Thompson (1975) found no effects, however, of a 1-hour exposure to loud noise, but Carter and Beh (1989) were able to significantly elevate cardiovascular parameters from 1 hour of exposure, as long as participants simultaneously worked at a difficult task.

This latter finding, along with other experimental findings reviewed earlier on the multiplicative effects of noise and task demands on cardiovascular and neuroendocrine functioning, is interesting to consider in light of a small number of occupational noise studies that have also incorporated additional measures of working conditions. A Russian industrial study reviewed by Welch (1979) found elevated cardiovascular functioning in a noisy manufacturing plant among workers

with higher levels of workload demands. Workers with low workloads did not reveal any cardiovascular correlates of occupational noise exposure. Parallel results were recently uncovered in a longitudinal study (Melamed, Boneh-Kristal, & Froom, 1999). Cottington, Matthews, Talbot, and Kuller (1983) also reported a significant interaction of job stress and noise on diastolic blood pressure. Job stress was associated with higher blood pressure in a noisy manufacturing plant but not a quiet one with good controls for SES and cardiovascular risk. Similarly, Lercher, Hortnagl, and Kofler (1993) found that annoyance with noise at work had a small positive association with diastolic blood pressure. This relation was significantly amplified, however, among workers who also reported job dissatisfaction and low levels of social support on the job. Occupational exposure to noise levels may also interact with shift work. Ottmann, Rutenfranz, Neidhart, and Boucsein (1987) and Cesana et al. (1982) both found elevated catecholamine levels related to noise levels at work but only among workers on rotating shifts. Nonshift workers in noisy work areas did not reveal these associations. Lercher et al. (1993) also found higher levels of blood pressure among workers annoyed by noise who also engaged in shiftwork relative to nonshiftwork employees.

There has been a small number of industrial studies or simulation studies with prolonged noise exposure that have examined neuroendocrine and other biochemical markers of stress rather than cardiovascular functioning. Mixed results have been uncovered with no relation between noise exposure and cholesterol (Brown, Thompson, & Folk, 1975), cortisol (Brandenberger, Follenius, & Tremolieres, 1977; Cavatorta et al., 1987; Slob, Wink, & Radder, 1973), and with one or more catecholamines (Carlestam et al., 1973; J. Osguthorpe, Mills, & N. Osguthorpe, 1983; Paulocci, 1975; Slob et al., 1973). Other studies have uncovered significant, although typically small, associations between noise levels on the job or from simulated exposures and various psychophysiological indicators, such as reduced urine volume and 17-ketosteroid levels (Gibbons, Lewis, & Lord, 1975), elevated fatty acids (Ortiz et al., 1974; Promiewska et al., 1972), higher levels of cholesterol (Cantrell, 1974; Ortiz et al., 1974; Rai, Singh, Upadkyay, Patil, & Nayer, 1981), increased epinephrine levels (Cavatorta et al., 1987; Ortiz et al., 1974; Slob et al., 1973), elevated cortisol (Cantrell, 1974; J. Osguthorpe et al., 1983; Rai et al., 1981), and increased levels of ACTH and oxytocin (Fruhstorfer & Hensel, 1980). Although there are more published positive findings, it is important to keep in mind that most of these noise and biochemical studies find small changes, and null results are more difficult to get published. On the other hand, there is also a large animal literature generally consistent with significant biochemical outcomes from acute noise exposure under controlled conditions (B. Welch & A. Welch, 1970).

Increasingly, researchers have turned their attention to community studies of noise and psychophysiological parameters, particularly blood pressure. Traffic noise levels appear to have no relation to blood pressure in community samples (Elwood, Ising, & Babisch, 1993; Lercher & Kofler, 1993; Knipschild & Salle, 1979) or show a small positive associa-

tion (von Eiff, Friedrich, & Neus, 1982; Neus, Ruedel, Schulte, & von Eiff, 1983; Wu, Chiang, Huang, & Chang, 1993). Regecova and Kellcrova (1995) found that traffic noise both at home and at school was associated with elevated blood pressure among 3- to 7-year-olds. Interestingly, there were multiplicative effects as well of school and home noise. The Neus study is noteworthy because it is longitudinal. The Wu study bears mention as well since they found that traffic noise elevated young children's blood pressure as a function of hearing status. Congenitally deaf children were unaffected by road noise, whereas their able-hearing counterparts suffered small elevations. Herbold, Hense, and Keil (1974) noted a small positive relation between traffic noise levels and hypertension prevalence among adults and Babisch, Fromme, Beyer, and Ising (1996) found elevated overnight neuroendocrine stress hormones. Simulated exposure to traffic noise under controlled conditions elevates both cardiovascular and neuroendocrine activity as a function of sound intensity (Ising, Dienel, & Markert, 1980; Osada, Ogawa, Hirokawa, & Haruta, 1973). Ising's study is particularly interesting because, as in several of the acute noise exposure studies noted earlier, he found that exposure to simulated traffic noise while working had significant effects on both cardiovascular and neuroendocrine levels, especially when mental loads were higher. In one of the more rigorous tests of ambient noise exposure and cardiovascular health, Peterson, J. S. Augenstein, Tanis, and D. G. Augenstein (1981) were able to produce sustained, elevated arterial blood pressure in monkeys exposed for long periods of time to simulated recordings of aircraft and traffic noise played at typical ambient levels ($L_{eq} = 78$). Their work also showed that these monkeys sustained no hearing damage.

Studies of airport noise, which is typically louder and less predictable than road traffic noise, generally find stronger associations between noise exposure and elevated cardiovascular functioning in comparison to the road traffic noise studies. Most studies have focused on children rather than adults, which might also explain the generally more consistent, positive results than those uncovered in the road traffic noise literature.

Knipschild (1977a) found a dose-response relation between community airport noise exposure and hypertension among adult residents in Amsterdam. Two studies of simulated, military aircraft flights at low altitude have shown significant increases in blood pressure among elderly residents (Michalak, Ising & Rebentisch, 1990) and in catecholamines among middle-aged adults (Maschke, Breinl, Grimm, & Ising, 1992). Several studies have found significant relations between exposure to aircraft noise and elevated blood pressure in children (Cohen, Evans, Krantz, & Stokols, 1980; Cohen et al., 1986; Evans, Hygge & Bullinger, 1995; Ising et al., 1990; Karagodina, Soldatkina, Vinokur, & Klimukhin, 1969; Karsdorf & Klappach, 1968; Schmeck & Poustka, 1993). Several of these studies have very thorough statistical controls for socioeconomic status. One study has found no relation between airport noise levels and blood pressure (Cohen, Evans, Krantz, Stokols, & Kelly, 1981), but these data were explained by selective attrition (persons in noisy areas with

the highest levels of blood pressure left the area). Roche, Chumlea, and Siervogel (1982) found no association between ambient noise exposure in suburban communities with no nearby airports or major highways. This study is flawed because of unreliable blood pressure measurement procedures and use of self-reports for noise exposure estimation.

Evans and colleagues (1995) also investigated reactivity to a noise source, as well as chronic neuroendocrine activity levels as a function of community airport noise exposure. As shown in Table 20.1, they found evidence of elevated catecholamine activity, but no shifts in cortisol among elementary schoolchildren living in the flight path of a major international airport. Of further interest, children chronically exposed to noise appeared less reactive to an acute noise source while reading.

Ising and his colleagues found parallel trends for epinephrine, but not norepinephrine, and also found elevated cortisol in two sets of studies with adults that simulated exposure to night-time aircraft operations (Maschke, Ising, & Arndt, 1995). Of additional interest, in one study they generated a dose-response function between elevated overnight hormonal levels and sound intensity levels. Finally, Evans, Bullinger, and Hygge (1998) replicated their cross-sectional aircraft noise and young children's health findings in a prospective, longitudinal study of children living in the vicinity of the new, Munich international airport.

Immune Function

A large number of animal studies have utilized noise as a stressor to investigate altered immune function. The results, like those of the few human studies are quite mixed (Bly, Goodard, & McLean, 1993). Sieber et al. (1992), for example, found that uncontrollable but not controllable noise significantly decreased natural killer cells among healthy male subjects; Weisse et al. (1990) found the opposite pattern with controllable noise causing lymphocyte resistance to mitogens to drop.

Coping Behaviors

An alternative pathway by which noise and other environmental stressors may impact physical health is the exacerbation of substance abuse. Cigarette smoking and alcohol consumption both increase under stress (Cohen et al., 1986). In the presence of loud noise, nicotine ingestion reduces muscle tension (Hutchinson & Emley, 1973) and accelerates habituation (Friedman, Horvath, & Meares, 1974). In a

particularly interesting study, Cherek (1985) demonstrated a dose-response function between cigarette smoking (objective, experimental measures) and controlled exposures to varying noise levels (60-90 dBA).

Psychological Health

Several different types of studies have examined chronic noise exposure and mental health. The first set of studies explored possible relations between psychiatric admissions and aircraft noise exposure with decidedly mixed results. Several studies have found positive correlations between admission rates and high noise exposure (Abey-Wickrama, A'Brook, Gattioni, & Herridge, 1969; Herridge & Chin, 1972; Jenkins, Tarnopolsky, & Hand, 1981; Meecham & Smith, 1977). Nonsignificant relations have been found by Gattioni and Tarnopolsky (1973), and Jenkins, Tarnopolsky, Hand, and Barker (1979) found an inverse relation between noise levels and psychiatric admissions in the same region (Heathrow, to the West of London) utilized by Abey-Wickrama and by Jenkins et al. (1981). Kryter (1990), in a further analysis of some of Jenkins' data, discovered large ethnic differences that might have explained Jenkins' puzzling findings. Many of these studies have poor controls for social class and all are cross-sectional.

Self-reports of psychological distress were unrelated to road traffic noise levels in two cross-sectional studies (Tarnopolsky & Morton-Williams, 1980; Tarnopolsky, Watkins, & Hand, 1980) and in a prospective, longitudinal study (Stansfeld, 1993). The absence of support for a link between road traffic noise exposure and psychological health could be due, in part, to noise measurement. Halpern (1995) found that peak noise levels predicted several indices of psychological health, controlling for socioeconomic status of residents. Mean levels of traffic noise had no mental health correlates. Physician treatment for psychological problems, as well as use of hypnotic drugs, was associated with aircraft noise around Amsterdam (Knipschild, 1977b). Koszarny et al. (1981) demonstrated a similar relation, but only among women. Knipschild and Oudshoorn (1977) also found a clear relation among prescription rates for tranquilizers and aircraft noise over a 7-year period. Moreover, these authors found longitudinal trends in use of hypnotic pharmaceuticals that tracked changes in noise levels in airport impact zones. At the same time, they noted lower and consistently similar utilization rates among quiet neighborhoods of comparable socioeconomic composition. Grandjean, Graf, Lauber, Meier, and Muller (1976) found a dose-response function linking airport noise exposure to self-reported use of sleeping pills and tranquilizers. Watkins, Tarnopolsky, and Jenkins (1981), however, could not replicate the linkages between drug usage and aircraft noise exposure. One study has also uncovered a coarse dose-response function between occupational noise exposure and psychological symptoms among blue-collar workers (McDonald, 1989). Interestingly, in light of earlier work on crowding, social support and psychological health, Mc Donald also noted that impaired interpersonal relationships at work appeared to play a role in the mental health-noise links.

TABLE 20.1
Twelve-Hour, Overnight Neuroendocrine Measures

Variable	Quiet	Noisy
Epinephrine	368.62 ng/hr	526.36 ng/hr
Norepinephrine	766.22 ng/hr	1,108.82 ng/hr
Cortisol	3.62 ug/hr	3.75 ug/hr

Motivation

Interestingly, the initial study of helplessness and human beings utilized inescapable noise as the induction stimulus. Hiroto (1974) demonstrated that short-term exposure to inescapable noise induces helplessness. Adults were exposed to noise or quiet during an initial phase of an experiment. Half of the noise subjects could avoid the noise by learning an avoidance response. For the other half of the noise subjects, the noise was inescapable. The groups were then tested in a similar situation where noise could easily be avoided by a simple manual response. A second series of experiments replicated Hiroto's findings and also demonstrated that the helplessness induced by inescapable noise generalized to persistence on subsequent task performance (Hiroto & Seligman, 1975). Subjects exposed to inescapable noise exhibited significantly greater helplessness in the second testing phase, regardless of the similarity of the helplessness induction and testing phase (Hiroto & Seligman, 1975). Furthermore, the helplessness effects of inescapable noise were greater for external locus of control individuals (Hiroto, 1974). Krantz, Gikass, and Snyder (1974) found similar results in two studies of inescapable versus escapable noise. One final detail of Hiroto and Seligman's work worthy of note is that the learned helplessness effects of inescapable noise were quite similar to the induction of helplessness produced by exposing subjects to insoluble concept formation problems.

A large number of studies, initiated by Glass and Singer's pioneering work on perceived control and stress (1972) have examined performance aftereffects, immediately following exposure to uncontrollable noise. The basic paradigm includes exposing participants to noise while working on a cognitive task for a period of about 30 minutes. The participant then leaves the room and is asked to do another, apparently unrelated task where noise is no longer present (see Cohen, 1980, for an overview of this paradigm). Uncontrollable noise causes deficits in task persistence on puzzles (Gardner, 1978; Glass & Singer, 1972; Glass, Singer, and Friedman, 1969; Percival & Loeb, 1980; Sherrod, Hage, Halpern, & Moore, 1977; Wohlwill, Nasar, DeJoy, & Foruzani, 1976). Work by Glass and Singer (1972) also showed that the controllability, and to a lesser extent the predictability, of the noise is a critical component of these aftereffects. In a test of the external validity of the initial Glass and Singer findings, Moran and Loeb (1977) utilized tape-recorded aircraft noise and found, unexpectedly, that such noise did not appear to induce aftereffects in the laboratory. Percival and Loeb (1980) reasoned that perhaps airport noise, because of its temporal qualities, is rather predictable. Thus, they replicated the original Moran and Loeb finding utilizing the same stimuli, but of particular interest, found that when the aircraft noise bursts were sudden rather than the typical slow onset pattern of an approaching aircraft, negative aftereffects could be reliably produced. Rotton, Olszewski, Charleton, and Soler (1978) also showed that meaningful speech rather than noise could induce the same negative aftereffect. Evans et al. (1996) indicated that these negative aftereffects are amplified if exposure to uncontrollable noise occurs among subjects already under psychological stress. Finally,

Glass and Singer (1972) found that uncontrollable noise interferes with subsequent proofreading accuracy.

A small number of studies has also examined possible relations between chronic noise exposure and susceptibility to helplessness. Evans et al. (1995) adapted the Glass and Singer aftereffects puzzle for young children. They found that children living in high airport noise zones were less likely to persist at solving line tracing puzzles than their quiet community counterparts. Cohen and colleagues (Cohen et al., 1980, 1981) found that aircraft noise-exposed children were significantly less likely to solve a difficult, challenging puzzle than quiet comparison groups. Of particular interest, noise-impacted children were also more likely to simply give up on the puzzle before the allotted 4 minutes had passed. Fifteen percent of children from noisy schools failed the puzzle by giving up in comparison to only 2% of children from quiet schools. It is worth noting that the puzzles were designed and pretested to be fun and engaging to elementary-aged schoolchildren. These effects were replicated by Cohen and colleagues and similar trends were also found for home noise levels (Cohen et al., 1986). Both the Evans and Cohen studies had well-matched SES comparison groups. Moch-Sibony (1984) found very similar results in kindergarten children exposed to higher levels of aircraft noise in Paris. Wachs (1987) also showed that infants exposed to more noise at home manifest less mastery-oriented play as indexed by a standardized observation instrument. Of additional interest, teachers in noisy schools frequently report more difficulties motivating students than do teachers from quiet schools (see Evans & Lepore, 1973b, for a review). Finally, Cohen et al. (1986) uncovered a relation between children's willingness to relinquish choice and chronic noise exposure. Children from noisy schools relative to quiet schools were significantly more likely to allow an experimenter to choose a reward at the conclusion of their experiments rather than make their own choice.

Summary

Both industrial and community studies find no clear, consistent pattern of data on noise and morbidity. Similarly, data on acute noise exposure and altered immune functions are mixed. Although not plentiful, there is a confluence of findings suggestive of noise impacts on in utero development that warrant followup. Several studies point to noise as a factor in elevated smoking.

Acute noise produces short-lived elevations in cardiovascular and neuroendocrine functioning. Recent research suggests, however, that individuals sensitive to noise as well as situations with high workload demands can diminish and perhaps even block such habituation. A plethora of methodologically weak, occupational noise and health studies reveal decidedly mixed findings on noise and blood pressure. Some longitudinal studies indicate small, positive associations between occupational noise exposure and blood pressure elevations. Road traffic noise appears to have no significant impact on blood pressure of community residents, but persons living in the proximity of airports, particularly children, are at risk

for elevated blood pressure. The clinical significance of these elevations is unknown at this time.

Data on noise and psychological health are unclear. The preponderance of poorly designed studies links community noise levels to rates of psychiatric illness. There are better studies indicating some link between community noise exposure and utilization of pharmaceutical hypnotics. Both laboratory and field studies reveal that noise, particularly uncontrollable noise, can contribute to diminished motivation related to learned helplessness. Children chronically exposed to noise may be particularly susceptible to this phenomenon.

DISCUSSION

Application of the construct of psychological stress to examine the role of the physical environment in human health has proven useful in the case of crowding and noise. The primary contributions to date have been the identification of stress-related outcome measures likely to be related to environmental stressors and the preliminary development of a conceptual model for thinking about how and under what conditions noise, crowding, and other environmental stressors might adversely impact human well-being.

Conceptual Issues

A central deficiency has been an inattention to the role of underlying psychophysiological processes or social resources in the environmental stressor-disease link. In searching for answers to the question, why does crowding or noise cause disease?, there are very little data that has tested mechanisms like elevated cardiovascular functioning or diminished self-efficacy. What the data generally show, as depicted in Fig. 20.2, is a broad set of outcome measures independently assessed.

More studies are needed that simultaneously investigate physical or psychological health outcomes and one or more underlying processes in the same sample of individuals. For example, Evans and Lepore (Evans et al., 1989; Evans & Lepore, 1993a; Lepore et al., 1991) showed evidence for the model shown in Fig. 20.3—namely, that high residential density causes deterioration in social support resources, which in turn accounts for the linkage between density and psychological ill health.

There are an unbelievably large number of studies of noise and cardiovascular functioning (principally blood pressure) that have not also looked at some disease endpoint. Similarly, no studies have examined crowding, immune function, and physical morbidity.

Several psychophysiological mechanisms are prime candidates for more in-depth scrutiny as intervening processes that could link environmental conditions to ill health. Alterations in neuroendocrine functioning affect cardiovascular activity, primarily via adrenomedullary action as well as alter immune functioning via adrenocortical pathways (Baum & Grunberg, 1995).

Cardiovascular reactivity is another process warranting analysis. Two viable, competing hypotheses exist. Sustained, chronic exposure to uncontrollable, environmental stressors

like crowding or noise may deplete the organism's ability to respond adequately to challenge with cardiovascular mobilization (Dienstbier, 1989). Alternatively, heightened sensitivity and vigilance from chronic stressor exposure might exacerbate reactivity (Krantz & Manuck, 1984).

Learned helplessness and other motivational processes related to chronic environmental stressor exposure have not been adequately developed. It seems clear that one of the potentially most injurious aspects of chronic environmental stressors is their intractability. Several aspects of motivation and chronic environmental stress warrant additional research. The role of attributional processes, which is well documented in the helplessness literature, has not been applied to environmental stress research. It is clear that attributional processes are salient to environmental stressors like noise and crowding. Noise annoyance is strongly affected by attributions about the origins of noise stimuli, as well as their perceived health impacts (Koelega, 1987). Feelings of arousal induced by personal space invasions (Worchel & Teddlie, 1976), expectancies (Schmidt & Keating, 1979), or informational cues (Langer & Saegert, 1977; Paulus & Matthews, 1980) can all be attributed to crowding or other environmental conditions with varying consequences. The potential interplay among environmental stressors and uncontrollability, helplessness, and negative health outcomes (such as depression) is an area ripe for further study. Motivation or effort to maintain task performance or productivity under suboptimal conditions may be a salient factor, as well, in determining the long-term health consequences of chronic exposure to adverse environmental conditions. Several noise studies both in the laboratory and the field, as well as one crowding study indicate that task performance can be sustained under adverse conditions but at a "cost" of psychophysiological activation. The long-term health consequences of people expending additional effort to do their job when the environment is not optimal is an important and unresearched topic.

Studies of underlying psychosocial processes, such as social support or control, also raise provocative conceptual issues about environment, stress, and coping. Social support and control have each traditionally been conceptualized as exogenous factors that moderate stressor-outcome relations. As can be seen herein, however, chronic exposure to crowding or to noise directly effects social support and control processes, respectively. These psychosocial processes mediate rather than moderate the impacts of these chronic environmental demands. Other chronic stressors may have similar effects on coping resources.

In considering hypothetical mechanisms, it is also prudent to carefully scrutinize the traditional practice of statistically controlling risk factors in environmental epidemiology. For example, several noise and coronary heart disease investigations control for smoking levels. However, what if noise exposure increases smoking as a coping device, as suggested by some studies already reviewed? By statistically partialling out a "risk" factor, a psychologically relevant process that may underlie the noise-health link has been eliminated.

At a more abstract level, the construct validity implications of statistical controls or the practice of random assign-

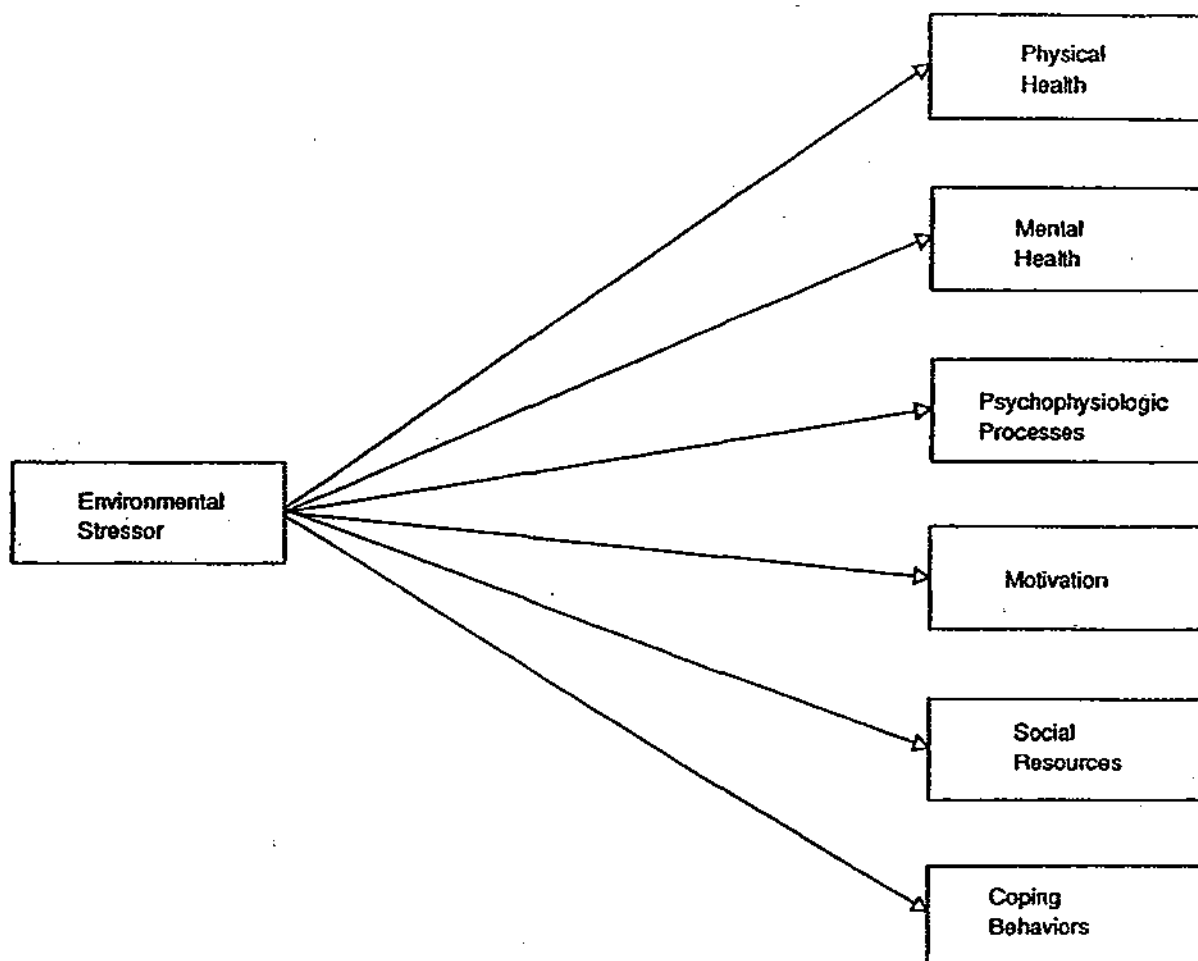

FIG. 20.2

FIG. 20.3

ment in experimental studies of stress and health should be carefully considered. By removing environmental stressors from their natural context (i.e., poverty, other suboptimal environmental factors) for the purposes of study, ecological validity of the stressor–health relation may be distorted. Perhaps crowding and poverty together or noise and certain job requirements together, respectively, lead to pathology. By isolating one independent variable either through statistical or experimental design means for purposes of causal modeling, the actual incidence of adverse outcomes from suboptimal en-

vironmental conditions may be dramatically underestimated (Lepore & Evans, 1996).

It might also be valuable to conceptualize the physical environment not only as a source of stress but also as a source of coping resources (Becker, 1990). Research on coping, like stress, tends to overly focus on intrapsychic mechanisms, missing the potential role of the social and physical environment to promote or interfere with health. For example, research on crowding suggests that floorplan layouts that incorporate greater intervening, hierarchically arranged

spaces, buffer the negative effects of residential crowding on psychological distress (Evans, Lepore, & Schroeder, 1996). Similarly, children in crowded homes who have a place where they can spend some time by themselves appear to suffer fewer negative outcomes (Wachs & Gruen, 1982).

Although children exposed to multiple risk factors are more likely to suffer adverse physical and mental health outcomes, some children are more resilient than others (Rutter, 1987). Bradley and colleagues (1994) found that low residential density was a significant, independent, protective factor among poor, low birth weight babies tested 1 and 3 years later on a wide array of physical and psychological health measures.

Methodological Issues

In addition to some of the conceptual issues associated with statistically controlling for risk factors, statistical approaches that partial out variables in order to "control" for possible confounding effects are also fraught with analytic problems. Statistical models that partial or covary out variables are based on the assumption of no interaction between the independent variable and the potential control variable on the outcome. Controlling for social class, for example, presupposes that noise or crowding do not interact with social class to affect health or well-being. The same statistical problem may occur with controls for certain risk factors, such as family history of coronary heart disease, hypertension status, or age, to name some common examples. Utilization of analysis of covariance or its regression equivalents assumes that the slopes of the respective regression lines between the outcome variable and the independent variable and the covariate (partial b) are parallel (i.e., no statistical interaction). Researchers should not employ covariance or analogous regression procedures to control for risk factors or contextual factors, such as socioeconomic status, without first assessing this basic statistical assumption.

Another analytic issue concerns effect size considerations. When the correlation coefficient between noise exposure and blood pressure, for example, is squared, not a lot of variance is explained. But this is also true if the same is done for cigarette smoking and lung cancer. It is also true that the variance explained in mental health by crowding is on the same order of magnitude as the variance explained by income (Evans et al., 1998; Gove & Hughes, 1983). Critics of the apparently small role of the physical environment in health need to grapple with this issue more in comparative, rather than in absolute, terms.

There is critical need for prospective, longitudinal designs in the field. There is only one crowding study incorporating such a design (Lepore et al., 1991) and just a handful of industrial studies of noise and health that incorporate a longitudinal component. Self-selection into noisy or crowded environments, as well as possible spuriousness, loom as major threats to internal validity in most of the field studies reviewed herein. Too many cross-sectional field studies exist. Furthermore, not enough integrated research programs have examined the same environmental stressor and health in the lab and in the field. The value of integrating lab and field work is illustrated by Cohen and colleagues' work on aircraft noise and

children where laboratory-based concepts and measures were brought to bear on the study of chronic, community noise exposure (Cohen et al., 1986).

Caution is needed in generalizing from aggregate level, epidemiological studies to individual health responses to the physical environment. Several examples of this ecological fallacy were previously reviewed, particularly in crowding field studies, where people per room as indexed by census tract did not yield the same pattern of results as when individual health measures were assessed. Parallel trends were noted in the noise and health literature (Lercher, 1996). One reason aggregate-level comparisons can be misleading is related to exposure estimation. Large degrees of variance in exposure are truncated into a single estimate of exposure when aggregate level data are examined. Furthermore, the actual environment as experienced is even further removed from the exposure metric in comparison to individual residential or work environment assessments.

The problems of exposure estimation and adequate representation of physical stressors in studies are common in the environmental stress literature. Many studies have only gross estimates of actual exposure to the physical stressor. Crowding and noise are typically estimated indirectly and do not account for individual movement throughout the day across settings. One indication of the importance of this issue is found in the noise literature where several studies on industrial noise show that duration of exposure is a critical variable. Similarly, utilization of hearing protection affects noises and health findings in industrial settings. Residential room location can also impact noise exposure (Lercher, 1996). An interesting example of the importance of exposure estimation comes from a recent study by Maxwell (1996) of crowding in preschoolchildren. Children in more crowded day-care centers had greater behavioral and emotional problems only if they also lived in crowded homes.

Moreover, the range of environmental variables in many studies is often truncated and/or the distribution of environmental exposures is badly skewed. Both of these problems strain the general linear model that forms the underlying statistical basis employed in most studies of the physical environment, stress, and health. For example, many studies of crowding have hardly any people in homes with more than 1.5 persons per room. Most laboratory studies expose people to quiet or noise and several community noise studies transform continuous data into a noise/quiet dichotomy. Badly skewed data, as well as use of dichotomous categories, reduce statistical power.

Furthermore, there is some indication of threshold effects for noise and crowding health effects. Recall for example some recent evidence that traffic noise above 65 dBA Leq appears necessary before cardiovascular risk elevates. This nonlinearity also adversely affects statistical power. Studies of traffic congestion and health outcomes indicate that log transformations (Halpern, 1995), or use of indices such as percentage of time at high congestion levels (Evans & Carrere, 1991), predict outcomes significantly better than do mean levels of exposure. This nonlinearity can also appear at the opposite end of the environmental exposure spectrum. Living alone is associ-

ated with psychological impairment as well as low social support (Gabe & Williams, 1987; Galle et al., 1972). Crowding studies that calculate persons per room as the density metric that include people living alone distort the estimate of association between crowding and health outcomes.

Outcome measures are also wanting. Several studies of psychological health employed one item or scales of unknown psychometric properties. Studies of health sorely need standardized, sensitive indicators. Immune function would be a particularly valuable adjunct to environmental morbidity studies. Several studies of blood pressure incorporated one or two readings, often taken in a medical setting. Such data are unreliable and of questionable validity.

Health psychology has demonstrated that individual, biological, and personological characteristics are central to understanding health and disease. A smaller body of work within health psychology has also examined the potential role of sociocultural factors in human health. Hopefully, this chapter has directed attention to the potential direct, indirect, and interactive roles the physical environment can play in health and human behavior.

ACKNOWLEDGMENTS

Preparation of this chapter was partially supported by grants from the National Institutes of Health (1 RO1 HL47325-01) the National Science Foundation (BNS-8920483) and the U.S. Department of Agriculture (Hatch-NY 327407). I am grateful to Jana Cooperman and Tamir Ebbin for bibliographic assistance. I thank Steve Lepore, Paul Paulus, and Shirley Thompson for critical feedback on earlier drafts.

**CHRONIC NOISE EXPOSURE AND PHYSIOLOGICAL RESPONSE:
A PROSPECTIVE STUDY OF CHILDREN LIVING
UNDER ENVIRONMENTAL STRESS**

Gary W. Evans,¹ Monika Bullinger,² and Staffan Hygge³

¹Cornell University; ²Universitätskrankenhaus Eppendorf, Hamburg, Germany; and ³Kungl Tekniska Högskolan, Gävle, Sweden

Abstract—Chronic exposure to aircraft noise elevated psychophysiological stress (resting blood pressure and overnight epinephrine and norepinephrine) and depressed quality-of-life indicators over a 2-year period among 9- to 11-year-old children. Data collected before and after the inauguration of a major new international airport in noise-impacted and comparison communities show that noise significantly elevates stress among children at ambient levels far below those necessary to produce hearing damage.

People typically characterize environmental issues as physical health or technological problems. But the physical environment may also have adverse psychological impacts. Suboptimal environmental conditions, such as noise and crowding (Cohen, Evans, Stokols, & Krantz, 1986; Evans & Cohen, 1987), air pollution (Evans, 1994), or disasters (Baum & Fleming, 1993), may elicit psychological coping reactions, including cardiovascular and psychoneuroendocrine activation (Baum, Grunberg, & Singer, 1982; Frankenhaeuser, 1986; Lundberg, 1984). In the present article, we provide prospective, longitudinal evidence that chronic noise elevates psychophysical stress and depresses perceived quality of life.

Although noise can cause hearing deficits (Kryter, 1994), nonauditory, stress effects of noise have not been demonstrated definitively because of methodological and conceptual limitations in prior research. Laboratory studies indicate that acute noise elevates psychophysiological stress (e.g., blood pressure, epinephrine), but these responses habituate rapidly (Evans, in press; Glass & Singer, 1972; Hygge, 1997).

Psychophysiological stress responses to chronic noise have been investigated in industrial settings and in communities proximate to highways and airports. These cross-sectional studies, unfortunately, are subject to an array of plausible alternative explanations, particularly self-selection bias. Although suggestive trends linking occupational noise exposure and hypertension exist, the designs of these studies are so weak that definitive conclusions cannot be drawn (Evans, in press; Thompson, 1993). Poor or nonexistent control groups, nonrigorous assessments of blood pressure (e.g., one reading while on the job), and insufficient estimation of noise exposure plague industrial studies of noise and cardiovascular parameters.

Community studies of aircraft noise reveal elevated psychophysiological stress among children (Evans, Hygge, & Bullinger, 1995; Evans & Lepore, 1993). All of these studies are cross-sectional and, with one exception (Evans et al., 1995), limited to blood pressure. Knipschild (1977) has also shown a dose-response function between noise exposure in the community and hypertension among adults around the Amsterdam airport. The most clear-cut evidence that noise causes ele-

vated psychophysiological stress comes from a primate laboratory study (Peterson, Augenstein, Tanis, & Augenstein, 1981). Simulated air- and road-traffic noise produced stable, elevated arterial blood pressure over a several-week period in the laboratory.

Many noise studies have obscured not only methodological issues, but also important conceptual issues. First, with few exceptions, investigators have not screened for hearing damage. One cannot presently say with any confidence whether stress correlates of community and occupational noise exposure are mediated by hearing loss. Second, nearly all the field studies have confounded acute and chronic noise exposure. Typically, testing has occurred in situ. If individuals are not tested under quiet, carefully controlled conditions, one cannot confidently attribute stress responses to chronic versus acute noise exposure.

The present study took advantage of a natural experiment created by the opening of a new international airport located in a rural area 35 km outside of Munich, Germany. Resting blood pressure, overnight levels of neuroendocrine hormones, and quality of life were measured over a 2-year period among elementary school children residing in the flight paths of this airport before and after its inauguration. Comparison groups of sociodemographically well-matched children from nearby rural communities were also assessed over the same time period.

METHOD

Subjects

Participants were 217 third- and fourth-grade children (mean age = 9.90 years at the study's onset) living either proximate to the new Munich International Airport or in nearby communities outside the noise impact zone of the new facility. The total of 217 participants reflects attrition of 10 and 14 children, respectively, from the noisy and quiet areas. Attrition was unrelated to the outcome variables.

The measures of noise were 24-hr dBA Leq, an unweighted mean of energy level expressed in decibels, and dBA L01, the dBA level exceeded 1% of the time over the sampling period (24 hr in the present case). The dBA scale is logarithmic, and the human observer experiences an increase in 10 dBA as approximately a doubling of loudness. Following inauguration of the new airport, dBA Leq equaled 62, with a dBA L01 of 73, in the noise-impacted communities. Among the quiet communities at the same time period, dBA Leq was 55, with a dBA L01 of 64. Prior to the opening of the new airport, dBA Leq was 53, with a dBA L01 of 63, in the airport communities, and noise levels were comparably low in the comparison areas (dBA Leq = 53, dBA L01 = 64).

Children in the quiet comparison communities were matched to the children in the noise-impacted communities according to socioeconomic status. Households did not differ in the type of occupation, $\chi^2(4, N = 197) = 8.91$; parental education, $t(214) < 1.0$; or family size, $t(214) < 1.0$. All of the children in the study were screened for normal hearing with an audiometric examination.

Noise Exposure and Physiological Response

Procedure

Testing occurred in a sound-attenuated, climate-controlled mobile laboratory parked outside the child's elementary school. A microphone (6 m above ground) interfaced with a B&K Model 4426 Community Noise Level Analyzer monitored 24-hr outdoor noise levels at the trailer. Data were collected 6 months prior to the opening of the new airport (Wave 1), 6 months after the opening (Wave 2), and again 18 months after the opening (Wave 3), for a total of three assessment phases per participant.

Resting blood pressure was assessed with an automated monitor (A & D Digital, UA 751) while the child sat comfortably with his or her right arm supported at heart height on a table. Baseline readings were calculated by taking the average of six resting indices taken on 2 consecutive days. On each day, four readings were taken after an orientation to the automated monitor, and the first reading was discarded. Reliability estimates for the six readings exceeded an alpha of .85 for both diastolic and systolic blood pressure.

Twelve-hour overnight urine samples were collected between 20:00 on the evening of the initial testing day and 8:00 the following morning. The container was kept refrigerated and contained a preservative. Parents returned the urine specimen container the next day to the trailer. Total volume was measured, and small replicate samples of urine were extracted and deep frozen at -70°C until assayed. Half of the replicates were also pH adjusted to reduce oxidation further for the catecholamine assays. Epinephrine and norepinephrine were assayed by high-performance liquid chromatography with electrochemical detection (Riggin & Kissinger, 1977). Cortisol was determined by a radioimmuno assay (Baxter Travenol Diagnostics, Cambridge, Mass.). (For further information about procedures for the collection and assay of urinary neuroendocrine samples, see Baum & Grunberg, 1995, and Grunberg & Singer, 1990.)

Quality of life was assessed by the KINDL, a valid and reliable index of the principal domains of quality of life (physical, psychological, social, functional daily life; Bullinger, von Mackensen, & Kirchberger, 1994). These domains were combined for the present analysis ($\alpha = .92$).

RESULTS

The data analytic strategy was to conduct a 2×3 repeated measures multivariate analysis of variance (MANOVA). The principal statistic of interest is the exact F test for the interaction of group (noise impacted vs. quiet) and time (Wave 1 vs. Wave 2 vs. Wave 3).

As can be seen in Table 1, blood pressure increased in the noise-impacted communities after Wave 1, with the opening of the new airport; much smaller changes occurred among the quiet, comparison communities. The interaction of group and time was significant for systolic blood pressure, MANOVA exact $F(2, 214) = 4.50, p < .01$, and marginal for diastolic blood pressure, $F(2, 214) = 2.83, p < .06$.

The overnight urinary neuroendocrine results are shown in Table 1 as well. Consistent with the elevations in blood pressure, both epinephrine, $F(2, 200) = 36.86, p < .001$, and norepinephrine, $F(2, 200) = 22.31, p < .001$, increased sharply among children living in the flight paths of the new airport after it opened; smaller increases were seen over the same period among the children residing in quiet communities. Changes in urinary cortisol over time were not systematically related to noise conditions, $F(2, 200) = 1.73, n.s.$ Degrees of freedom vary because of missing data.

As indicated in Table 2, quality of life declined significantly in the noise-impacted communities 18 months after the opening of the new airport, but remained relatively stable in the quiet, comparison communities, $F(2, 202) = 3.07, p < .05$.

Table 1. Measures of psychophysiological stress in the noise-impacted and quiet communities

Measure and community	Wave		
	1	2	3
Systolic blood pressure (mm Hg)			
Noise	97.2 (11.6)	101.6 (9.9)	102.4 (10)
Quiet	100.8 (8.9)	102.2 (8.9)	102.6 (12)
Diastolic blood pressure (mm Hg)			
Noise	60.5 (7)	63.2 (6.1)	64.4 (6.2)
Quiet	62.6 (7.1)	63.6 (6.4)	64.8 (6.8)
Epinephrine (ng/hr)			
Noise	229.2 (153.4)	328.1 (130.4)	341.9 (168.1)
Quiet	251.8 (57)	280.9 (64.6)	246.2 (83.7)
Norepinephrine (ng/hr)			
Noise	610.7 (338.6)	1,228.5 (659.7)	1,556.3 (703.6)
Quiet	660.0 (506.9)	879.7 (457.7)	950.7 (525.5)
Cortisol ($\mu\text{g/hr}$)			
Noise	3.56 (1.89)	4.36 (5.39)	5.14 (6.89)
Quiet	3.31 (1.89)	2.37 (6.14)	3.78 (2.89)

Note. The data shown are means, with standard deviations in parentheses.

Table 2. Quality of life in the noise-impacted and quiet communities

Community	Wave		
	1	2	3
Noise	110.3 (13.8)	112.4 (13.9)	104.8 (16.0)
Quiet	112.5 (16.4)	112.1 (17.0)	109.6 (15.5)

Note. The scale for the quality-of-life measure ranges from 40 to 200, with greater values indicating higher perceived quality of life. The data shown are means, with standard deviations in parentheses.

DISCUSSION

Chronic exposure to ambient aircraft noise elevates psychological stress in human beings. Children living proximate to the new Munich International Airport experienced significant elevations in resting blood pressure after the airport opened. During this same time period, well-matched children in nearby, similar communities experienced stable levels of resting blood pressure. The catecholamine data, which are consistent with the blood pressure effects, underscore the value of conceptualizing noise and other suboptimal environmental conditions as stressors. Elevated urinary catecholamines have consistently been shown to reliably and sensitively mark chronic exposure to stressors (Baum et al., 1982; Frankenhaeuser, 1986; Lundberg, 1984). Urinary cortisol has proven less reliable as an index of chronic stress exposure (Frankenhaeuser, 1986; Lundberg, 1984).

The self-report data show the same pattern, but with a delayed time course. Childrens' perceived quality of life dropped more markedly in the noise-impacted communities than in the quiet communities, but this drop did not occur until 18 months after the new airport opened.

As in any field study, some questions remain. We cannot disentangle the apparent effects of chronic noise from the uncontrollability of that exposure. Although the primary environmental change near the new airport was dramatic increases in sound levels, the surrounding community also witnessed increased land development, more road traffic, and the like.

Our prospective data add evidence to previous cross-sectional results that have shown elevated stress among adults and children working and residing, respectively, in chronically noisy environments. In young children, chronic noise exposure appears to cause increased psychological stress, as measured by cardiovascular, neuroendocrine, and affective indicators. These effects occur among children who suffer no detectable hearing damage while living in the immediate vicinity of an airport.

Acknowledgments—We are grateful to the families who cooperated with this research. We thank Sylvia von Mackensen, Markus Meis, Gerhard Helm, Gunnar Söderqvist, Christian Wigren, Nils Antoni, and Pat O'Keeffe for their dedication to this project. This research was partially supported by the Society for the Psychological Study of Social Issues, the National Institutes of Health (R01 HL 4732 01A), the Nordic Scientific Group for Noise Effects, the Swedish Environmental Protection Agency, and the Gertman Research Foundation. The second author was also supported by the DFG Heisenberg Fellowship.

Proposed chRDs for School Site Risk Assessment

Executive Summary

As mandated by Part 2 of the Health and Safety Code, section 901(g), the Office of Environmental Health Hazard Assessment (OEHHA) reviewed five chemicals to consider the development of child-specific reference doses (chRDs). This report summarizes OEHHA's review of pertinent scientific studies in proposing these chRDs. Any chRDs established as a result are intended for use in the risk assessment of proposed or existing California school sites.

OEHHA completed Part 1 of that mandate, which called for the identification of chemical contaminants commonly found at school sites and determined to be of greatest concern to children. The report, "Development of Health Criteria for School Site Risk Assessment Pursuant to Health and Safety Code, Section 901(g): Identification of Potential Chemical Contaminants of Concern at California School Sites," was posted on OEHHA's website in June, 2002. In summary, OEHHA identified seventy-eight chemicals that will likely be found as contaminants of California school sites and have the potential for causing adverse effects in children. This should be viewed as a living compilation – chemicals may be added or removed as new information becomes available.

OEHHA chose five chemicals from the compilation for an in-depth evaluation of non-carcinogenic effects: cadmium, chlordane, heptachlor and its metabolite heptachlor epoxide, methoxychlor, and nickel. The criteria used to select these chemicals for the first round of reviews are discussed in Chapter 1.

In reviewing the applicable scientific literature, OEHHA identified relevant quantitative studies from which to propose a chRD for each chemical. The chRD for the non-carcinogenic effects of cadmium is based on a 1999 study by Buchet et al. The authors reported a strong relationship between cadmium body burden and renal tubular dysfunction in adult humans. This study identified a lowest observed adverse effect level (LOAEL) of 1×10^{-3} mg/kg-day. From this LOAEL, OEHHA calculated a chRD of 1×10^{-5} mg/kg-day using an uncertainty factor of 30 (10 to account for human variability and 3 to extrapolate from the LOAEL to the no observed adverse effect level (NOAEL). A factor of 3 (rather than the usual default of 10) was used for extrapolating from a LOAEL to a NOAEL because the LOAEL was based on the minimal adverse effect observed. A child protective modifying factor of 3 was used to account for the child/adult difference in gastrointestinal absorption of cadmium for a combined uncertainty and modifying factors of 90.

The chRD for the non-carcinogenic effects of chlordane is based on a 1994 study by Cassidy et al. The authors demonstrated changes in sex-steroid mediated behaviors, including increased male-typical spatial abilities in female rats and increased male-typical mating behaviors in male rats, following pre- and postnatal exposure. This study identified a LOAEL of 0.1 mg/kg-day, from which OEHHA calculated a chRD of 3.33×10^{-5} mg/kg-day using an uncertainty factor of 3000 (10 for interspecies variability, 10 for human variability, 10 to extrapolate to the LOAEL from the NOAEL, and a modifying factor of 3 to account for an inadequate hematotoxicity/immunotoxicity and neurotoxicity database—toxicities to which children may be particularly sensitive).

The chRD for the non-carcinogenic effects of heptachlor is based on two studies. One is a 2001 study by Moser et al., which shows decreased performance on measures of cognitive function in male rats following pre- and postnatal exposure, through postnatal day 21. The other is a 2001 study by Smiałowicz et al., which shows suppression of the primary IgM and secondary IgG antibody responses following exposure during the last half of gestation through puberty. Both studies identified a LOAEL of 0.03 mg/kg-day. OEHHA calculated a chRD of 3×10^{-5} mg/kg-day using an uncertainty factor of 1000 (10 each for interspecies variability, human variability, and extrapolation from LOAEL to NOAEL). The chRD for the non-carcinogenic effects of heptachlor epoxide utilizes the same study selected by U.S. EPA for its reference dose (RfD) and OEHHA for its Public Health Goal (PHG.) A LOAEL of 0.0125 mg/kg-day for liver-to-body weight ratio was reported when adolescent dogs were fed heptachlor epoxide for 60 weeks (Dow Chemical Co., 1958). Since exposure was to adolescent animals, OEHHA utilized the U.S. EPA RfD for its chRD of 1.3×10^{-5} mg/kg-day and utilized the same uncertainty factor of 1000 (10 each for interspecies variability, human variability, and extrapolation from LOAEL to NOAEL).

The chRD for the non-carcinogenic effects of methoxychlor is based on two studies as well. One is a 1995 study by vom Saal et al., which demonstrates increased urine marking in male mice, an index of territorial behavior, subsequent to prenatal exposure. The other is a 1999 study by Welshons et al., which shows an increase in adult prostate size following prenatal exposure. The LOAEL identified from these studies is 0.02 mg/kg-day. OEHHA calculated a chRD of 2×10^{-5} mg/kg-day using an uncertainty factor of 1000 (10 each for interspecies variability, human variability, and extrapolation from LOAEL to NOAEL).

The chRD for the non-carcinogenic effects of nickel is based on the observed pup mortality in three reproductive studies – Smith et al., 1993, and Springborn Laboratories, 2000 a and b. In reviewing these three studies in totality, OEHHA concludes that the 1.1 mg nickel/kg-day (5 mg nickel sulfate hexahydrate/kg-day) dose constitutes the appropriate NOAEL. From this NOAEL, OEHHA calculated a chRD of 3.7×10^{-3} mg/kg-day, using an uncertainty factor of 300: 10 each for interspecies extrapolation and human variability) and a child protective modifying factor of 3 to account for the child/adult difference in gastrointestinal absorption of nickel.

Table ES 1 below compares the chRDs and U.S. EPA's RfD, which are based on studies in adult animals.

Table ES 1 OEHHA's chRD and U.S. EPA's RfD

	OEHHA's Proposed chRD (mg/kg-day)	U.S. EPA's RfD (mg/kg-day)
Cadmium	1×10^{-5}	5×10^{-4}
Chlordane	3.3×10^{-5}	5×10^{-4}
Heptachlor	3×10^{-5}	5×10^{-4}
Heptachlor epoxide	1.3×10^{-5}	1.3×10^{-5}
Methoxychlor	2×10^{-5}	5×10^{-3}
Nickel	3.7×10^{-3}	2×10^{-2}

These proposed chRDs were reviewed internally. OEHHA is currently releasing this draft report for external peer review and public comment. Any chRDs established by this process are intended for use in risk assessment of proposed or existing school sites in California.

1. Introduction

This report summarizes the first-year effort of the Office of Environmental Health Hazard Assessment (OEHHA) in developing health criteria for five selected chemicals for use in school-site risk assessment. The following provides the context for this effort.

1.1 Mandate

As part of a series of legislative provisions in California to protect children from exposure to environmental contaminants, OEHHA has been tasked under Health and Safety Code, Section 901(g), to fulfill the following directives:

1. On or before January 1, 2002, OEHHA, in consultation with the appropriate entities within the California Environmental Protection Agency (Cal/EPA), shall identify those chemical contaminants commonly found at school sites and determined by OEHHA to be of greatest concern based on criteria that identify child-specific exposure and child-specific physiological sensitivities.
2. On or before December 31, 2002, and annually thereafter, OEHHA shall publish and make available to the public and other state and local environmental and public health agencies and school districts, numerical health guidance values for five of those chemical contaminants identified until the contaminants identified have been exhausted.

1.2 Identification of Chemicals

The first part of the mandate, identifying those chemical contaminants commonly found at school sites and determined to be of greatest concern based on criteria that identify child-specific exposures and physiological sensitivities, was completed earlier. Available data did not permit us to definitively identify those chemicals that are commonly found at school sites and for which children have unique physiological sensitivities. However, we have identified a group of candidate chemicals that will likely be found as contaminants at school sites (200 chemicals), and another group where evaluation of review literature provided some indication the chemicals may have the potential for causing adverse effects on school-age children (198 chemicals). The methods used to implement the first part of the mandate are summarized below; a detailed description can be found in the OEHHA June 2002 report, "Development of Health Criteria for School Site Risk Assessment Pursuant to Health and Safety Code, Section 901(g): Identification of Potential Chemical Contaminants of Concern at California School Sites," which can be downloaded at:

http://www.oehha.ca.gov/public_info/public/kids/pdf/ChildHealthreport60702.pdf.

In identifying contaminants likely to be found at California school sites, OEHHA considered chemicals that have been targeted by federal and state agencies as being pervasive in pertinent environmental media, in addition to contaminants that have been found at school sites or were on the list of analytes for monitoring studies at California school sites. Using these criteria, OEHHA considered the following as candidate contaminants that are likely to be found at school sites:

- Ninety-four soil contaminants that have been reported in school site Preliminary Endangerment Assessments (PEA) and reviewed by the Department of Toxic Substances Control (DTSC).
- Ninety Toxic Air Contaminants that were emitted to, or detected in, California's ambient air.
- Sixty potential classroom contaminants targeted for monitoring by the Department of Health Services (DHS) and the Air Resources Board (ARB), as part of their Portable Classroom Program.
- Forty-seven toxic chemicals targeted by U.S. EPA in its National Human Exposure Assessment Survey (NHEXAS).
- Twenty-six contaminants targeted by U.S. EPA in its Total Exposure Assessment Methodology (TEAM) studies.

Because of overlap among the chemicals reported or targeted by the above federal and state agencies, the final compilation consists of 200 chemical contaminants likely to be found at school sites.

In identifying chemicals with potential child-specific sensitivities, OEHHA considered the following:

- Chemicals with one or more citations in review articles from the scientific literature indicating the potential for adverse effects on the development of the nervous, respiratory, reproductive, endocrine, or immune system.
- Chemicals that initiated cancer following exposure during the perinatal period or childhood.
- Chemicals identified as Proposition 65 Developmental and Reproductive Toxicants by OEHHA, excluding chemicals not likely to be found at school sites, such as pharmaceuticals. While Prop 65 deals with chemical exposures that occur during pregnancy, the inclusion of these Prop 65 chemicals are useful for screening chemicals that may also impact developing organ systems postnatally.

The final compilation consists of 198 chemicals to which children are potentially more sensitive, 87 of which are from the Proposition 65 list.

To aid in implementing the second part of the mandate, the two compilations were merged into one comprehensive list of 78 chemicals that met both criteria. This list is given in table ES 1 in OEHHA's June 2002 report (page 5) and will be updated as new data become available. The information obtained to produce this compilation is not

sufficient to conclude that the compiled chemicals are found in most schools or that children have a greater sensitivity compared to adults. The compilation has been prepared to assist OEHHA scientists in selecting chemicals for further in-depth review to determine if sufficient studies on toxicity to developing organ systems in the young exist to create a health guidance value specific for children. The list has no regulatory status.

1.3 Numerical Health Guidance Values

The second part of the mandate, which is the subject of this report, requires OEHHA to annually publish numerical health guidance values for five of those chemical contaminants identified in the June 2002 report until the contaminants identified have been exhausted. In order to prioritize chemicals from the compilations generated in Phase I for in-depth review, OEHHA outlined the following criteria, which was also described in the June 2002 report, for selecting chemicals for in-depth reviews. It should be emphasized that these four criteria are not permanent, but are being used to help us prioritize which chemicals to evaluate first. The compilation of chemicals will continue to be updated and reviewed.

1. Chemicals having a strong indication of their presence at school sites according to monitoring studies or other reliable sources.
2. Chemicals cited to have possible adverse effects in three or more of the systems that are undergoing critical development during childhood: the neurological, immunological, respiratory, reproductive, or endocrine systems.
3. Where applicable, chemical carcinogens with existing reference toxicity levels based on studies in adult animals that approximate the dose associated with a 10^{-4} (one in ten thousand) to 10^{-6} (one in a million) lifetime cancer risk.
4. Chemicals that other OEHHA programs have identified as a public health concern based on studies pertinent to children.

The first criterion addresses the possibility that children will be exposed to a given chemical while at school, since a chemical must have some probability of being found at a school site in order to warrant consideration under this mandate. The compilation of chemicals potentially found at school sites (OEHHA, 2002) was used to gauge the likelihood of a chemical being present at California school sites.

The second criterion helps select those chemicals that appear to have multiple effects on organ systems that are still undergoing development and maturation after birth. The nervous, immune, respiratory, reproductive and endocrine systems are being targeted because chemical insults at relatively low doses to any of these organ systems could

produce adverse effects, many of which may not be recognized until maturity (OEHHA, 2002).

In focusing on these critical organ effects, we have targeted non-cancer endpoints. In a separate task, OEHHA is developing a cancer evaluation methodology for children pursuant to HSC Section 901(e). Because that methodology will not be available until 2004, we are focusing on identifying and evaluating the non-cancer effects of chemicals. We will assess the cancer endpoint when the children's cancer methodology is developed.

The criteria for selecting chemicals identified in review articles as having effects on multiple developing organ systems was intended to increase the probability of identifying relevant literature during the in-depth search and review phase. Targeting chemicals with evidence of effects in three or more systems may miss an important developmental toxicant for which either only one system is affected or only one system has been adequately researched. However, given time and budget constraints, we felt this was an effective way to prioritize the chemicals on the list this year.

The third criterion helps target those chemicals that could conceivably be non-cancer risk drivers when new child-specific data were considered. If current data suggest that both carcinogenic and non-carcinogenic effects of concern occur at similar dose levels in adults, and studies on developing organ systems show that exposure may produce irreversible non-carcinogenic effects in children at dosages lower than those that are toxic to adults, then the chemical should have a high priority for further evaluation.

The fourth criterion allows us to build on related work done by other OEHHA programs. This year we utilized the peer-reviewed PHGs for drinking water contaminants developed by OEHHA. More information on the PHG process can be found at the web address <http://www.oehha.ca.gov/water/phg/allphgs.html>. The PHG effort provides an excellent springboard from which to conduct our current review for developing child-specific chRDs because the Pesticide and Environmental Toxicology Section's (PETS') reviews are recent and they cover the chemicals of interest.

Using the above criteria OEHHA selected cadmium, chlordane, heptachlor and its metabolite heptachlor epoxide, methoxychlor, and nickel as the first five chemicals for in depth review. Under contract with OEHHA, the Public Health Library at the University of California at Berkeley searched the following databases: PubMed, Toxline/DART, Excerpta Medicus (EMBASE), Chemical Abstracts, BIOSIS, International Pharmaceutical Abstracts (IPA), and ISI Web of Science. We searched by keywords that describe specific effects on developing organ systems. The keywords used in searching these databases are listed in Appendix A.

OEHHA evaluated the citations returned by the literature search (105 citations for cadmium, 65 for chlordane and heptachlor/heptachlor epoxide combined, 82 for methoxychlor, and 18 for nickel), and reviewed relevant qualitative background papers and quantitative studies. In addition, OEHHA reviewed pertinent studies cited in papers

obtained via the literature search. Because so few citations were returned for nickel, an alternate, very inclusive approach (discussed in Section 2.5) was used to ensure that we were not missing important studies.

1.4 Child-Specific Reference Dose (chRD)

U.S. EPA and the March of Dimes sponsored a workshop -- Identifying Critical Windows of Exposure for Children's Health -- in September 1999 to systematically review the state of knowledge on prenatal and postnatal exposures and subsequent outcomes (Environmental Health Perspectives Volume 108, Supplement 3, June 2000). In reviewing data on organ systems that are still undergoing development and maturation in children, workshop participants noted that data pertaining to children's sensitivities to environmental contaminants during various critical developmental periods are limited. In particular, very little attention has been given to peripubertal/adolescent exposures or adult consequences from childhood exposure. However, these limited data do suggest that children could be more sensitive than adults when their developing organ systems were exposed to harmful chemicals. For example, several developmental immunotoxicants (chlordane, dioxin, lead, and benzo[a]pyrene) demonstrate that perinatal exposures can produce toxicity at doses that do not affect adults and/or they produce irreversible changes which do not occur with adult exposure.

Endocrine disruptors, a group of chemicals that may produce differential toxicity to the young, have been the subject of much recent scientific and regulatory debate (Cranmer et al., 1984; Colborn et al., 1993; U.S. EPA, 1998). While not all chemicals reviewed in this first year are endocrine disruptors, the endocrine disruptors do pose a great concern because they could interfere with the proper hormonal signaling that is essential for growth and development of school children. An endocrine disruptor may be defined as an exogenous agent that interferes with the synthesis, secretion, transport, binding, action, or elimination of natural hormones in the body (U.S. EPA, 1997). Exposure to endocrine disruptors during critical "programming" periods in development, in contrast to exposure during adulthood, may produce irreversible effects on the reproductive, nervous, and/or immune system (Bigsby, 1999). In adulthood, these endocrine disruptors might only produce reversible effects by participating in the "seesaw" process of stimulation and feedback inhibition.

The effects of endocrine disruptors are more difficult to evaluate than chemicals which have a direct toxic effect on an organ system. Endocrine disruptors can act directly on hormone receptors of developing target organs, or they can act indirectly by interfering with the synthesis or metabolism of natural hormones. An endocrine disruptor having a direct interaction with either intracellular receptors or membrane-bound receptors can mimic a natural ligand by acting as an agonist, or if it inhibits binding, as an antagonist. The best known examples are methoxychlor, chlordecone (Kepone), DDT, some PCBs, and alkylphenols (Mueller and Kim, 1978; White et al., 1994; U.S. EPA, 1997). The antiandrogenic action of vinclozolin is the result of the affinity of its metabolites for the

androgen receptor (van Ravenzwaay, 1992; Kelce et al., 1994). O,p-DDT and chlordane inhibit binding to both estrogen and progesterone receptors (Laws, 2000).

An endocrine disruptor can have an indirect effect on a target organ if it changes the quantity of a hormone or the ratio of several hormones at target organs by altering hormonal storage and/or release, transport in the blood and clearance, or post-receptor activation. Many different mechanisms can produce these changes.

Disruption of normal signaling, whether it causes a direct effect on a target organ, or whether it alters hormone ratios or levels, can produce an adverse effect on a single organ system -- the reproductive, immune or nervous system -- if the disruption occurs during a critical period in development (Kavlock et al., 1996). Disruption of normal signaling can also produce adverse effects on multiple organ systems. For example, estrogen receptors can be found in the gonads, thymus, and brain; and the disruption of estrogen signaling could simultaneously affect the reproductive, immune, and nervous systems (Colborn et al., 1993; Diel, 2002). To complicate the matter further, one endocrine axis can impact another in a "cross-talk" (WHO, 2002). For example, in humans and some other mammals, most of the testosterone and estradiol circulating in the bloodstream are not bioavailable because of their binding to sex hormone binding globulins (SHBG). Not surprisingly, SHBG production is regulated by testosterone and estradiol (Prinsloo and Van Aswegen, 2000; Pugeat et al., 1996). However, via cross-talk, SHBG is also regulated by insulin. Thus, an insulin disruptor that causes an elevated insulin level would suppress SHBG production, leading to an increase in testosterone and estradiol bioavailability (Pugeat et al., 1996).

Given the complexity of hormonal signaling processes, it is also not surprising to find the relationship between dose and response to be another controversial issue. Endocrine disruptors often act by mimicking or antagonizing the actions of naturally occurring hormones that may be already at physiologically functional concentrations (WHO, 2002). The National Toxicology Program's Report of the Endocrine Disruptors Low Dose Peer Review concluded that biological changes occurred in the range of human exposures or at doses that are lower than those typically used in the EPA's standard testing paradigm for evaluating reproductive and developmental toxicity for endocrine active agents (<http://ntp-server.niehs.nih.gov/htdocs/liason/LowDosePeerFinalrpt.pdf>). Too little is known about the dose-response curves for immunotoxicity, neurotoxicity, or endocrine effects to decipher the independent or interactive effects of endocrine disruptors on these systems. The shape of the dose response curve varies with the endpoint and dosing regimen and it may be low-dose linear, threshold-appearing, or it may be shaped like an upright U or an inverted U (<http://ntp-server.niehs.nih.gov/htdocs/liason/LowDosePeerFinalrpt.pdf>; Markowski et al., 2001; vom Saal et al., 1997).

The above observations underscore some of OEHHA's challenges in implementing HSC Section 901(g) pertaining to the development of health criteria based on children's sensitivities. As discussed by Ginsberg et al. (2002) and Miller et al. (2002), the risks

that children incur from exposure to environmental contaminants could differ from adult risks as a result of the following factors:

- Greater exposure in young children from a higher inhalation and food ingestion rate per body weight; and greater contact with soil, house dust and other media that may contain contaminants.
- Pharmacokinetics differences between children and adults with respect to absorption, metabolism, clearance, protein binding, and volume of distribution, once exposure has occurred.
- Pharmacodynamic differences between children and adults; that is, the sensitivity of rapidly developing tissues/organs in children may differ from that in adults.

The exposure differences will be addressed under a separate task -- developing the school exposure assessment guidelines -- pursuant to HSC Section 901(f). Based on available pharmacokinetic and pharmacodynamic data, we will evaluate if existing U.S. EPA RfDs or OEHHA toxicity criteria are appropriate, or if child-specific ones should be proposed, for school-site risk assessment in California.

From a public health protection standpoint, OEHHA has adopted two policies in developing chRDs. First, in order to protect children from conception through the time they leave school, chRDs must consider school-aged children up to age 18; and infants and toddlers in daycare facilities located at school sites. Second, OEHHA opts to consider the most sensitive species and endpoints in our evaluations, meaning that the lowest LOAEL or NOAEL from available literature would be selected. Moreover, the paucity of data has underscored the reality that the databases for sensitive endpoints may be incomplete. An uncertainty factor for database deficiency will be considered as appropriate.

Our mandate, which is driven by environmental health policies, has charted OEHHA's course of action. We view this approach as an iterative process. Any chRD established will be subject to review and refinement as the state-of-the-science progresses.

2. Evaluation of Five Chemicals

This chapter is divided into five sections, one for each chemical reviewed in 2002. Each section provides information specific to the particular chemical, including background and exposure information; how the chemical meets our criteria for evaluation; existing pertinent health guidance values; findings from our literature review; and OEHHA's recommendation. The recommendation includes a discussion of the study (or studies) used in developing the chRD, the uncertainty and modifying factors used, the calculation, and the proposed chRD.

2.1 Cadmium

Cadmium is an important industrial chemical with diverse applications. It is used for the production of nickel-cadmium batteries, pigments, alloys, plastics, and synthetics. It is also used in metal plating. The Toxic Chemical Release Inventory of 2000 shows that 2,292 pounds of cadmium were emitted into the air, 792 pounds were discharged into surface water, 69,000 pounds were injected underground, and 663,895 pounds were released to land in the U.S. In comparison, 16 pounds of cadmium entered the air and 36,104 pounds were disposed of on land in California during 2000 (U.S. EPA, TRI2000).

Given its indestructible nature, cadmium persists in the environment, and can enter the food chain. OEHHA identified air, drinking water, soil, and food as the primary pathways for human exposure to cadmium (OEHHA, 1999a). U.S. EPA and ARB/DHS have deemed cadmium as a chemical of interest in their NHEXAS and Portable Classroom Study, respectively (OEHHA, 2002). ARB reported the occurrence of cadmium in California air and DTSC reported the presence of cadmium at 10 percent of the potential school sites reviewed by the Department, making it a relatively frequently observed contaminant.

In reviewing literature for the purpose of establishing a Public Health Goal (PHG) for cadmium in drinking water (OEHHA, 1999a), OEHHA found some evidence that cadmium may elevate blood pressure in both animals and humans. Renal toxicity of cadmium is well known. Cadmium tested positive in several mutagenic assays and in an epidemiological study; it was observed that individuals with higher levels of cadmium in their urine ($>3 \mu\text{g/L}$) had more frequent chromosomal aberrations in their lymphocytes. A number of studies in rats and mice indicated the developmental and reproductive toxicity of cadmium. Neurological and immune effects were also reported. Finally, tumors of the prostate, testes and hematopoietic system in the rat were associated with oral cadmium exposure; and human lung and prostate cancers had been associated with inhalation exposure. Thus, it is regarded as a potential human carcinogen by the oral route and a human carcinogen by the inhalation route.

OEHHA selected cadmium for an in-depth review in this first cycle not only from the standpoint of its exposure potential at school sites, but also because of its adverse effects

on various organ systems; some of which are still undergoing development in school children.

Pertinent Guidance Values

U.S. EPA RfD: 0.5 µg/kg-day (water) and 1.0 µg/kg-day (food)

U.S. EPA's RfD is based on cadmium's effect on the kidney. A concentration of 200 µg cadmium (Cd)/g wet human renal cortex is the highest renal level not associated with significant proteinuria (U.S. EPA, 1985). A toxicokinetic model is available to determine the level of chronic human oral exposure (NOAEL) which results in 200 µg Cd/g wet human renal cortex; the model assumes that 0.01 percent day of the Cd body burden is eliminated per day (U.S. EPA, 1985). Assuming 2.5 percent absorption of Cd from food or 5 percent from water, the toxicokinetic model predicts that the NOAEL for chronic Cd exposure is 0.005 and 0.01 mg Cd/kg-day from water and food, respectively (i.e., levels which would result in 200 µg Cd/g wet weight human renal cortex). Thus, based on an estimated NOAEL of 0.005 mg Cd/kg-day for Cd in drinking water and an uncertainty factor (UF) of 10 that accounts for intra-human variability, an RfD of 0.0005 mg Cd/kg-day (water) was calculated; an equivalent RfD for Cd in food is 0.001 mg Cd/kg-day.

U.S. EPA gives a high confidence to its cadmium RfD. The choice of NOAEL does not reflect the information from any single study. Rather, it reflects the data obtained from many studies on the toxicity of cadmium in both humans and laboratory animals. These data also permit calculation of pharmacokinetic parameters of cadmium absorption, distribution, metabolism and elimination.

OEHHA PHG: 0.07 µg/L (a safe dose of 1×10^{-5} mg/kg-day)

OEHHA deemed the Buchet investigation (Buchet et al., 1990) as the best study for use in developing a Public Health Goal (PHG) for cadmium in drinking water. The study avoided the healthy worker effect by performing a cross-sectional examination on 1699 Belgian subjects between the ages of 20 and 80 years. The investigators found a strong relationship between cadmium body burden and renal tubular dysfunction. They observed a risk of renal effects at or above the urinary excretion rate of 2 µg cadmium/24 hours. Assuming an oral absorption rate of 5 percent and a daily excretion rate of 0.005 percent of body burden, Buchet estimated that this excretion rate corresponded to a mean renal cortex concentration of about 50 ppm or 50 µg/g (wet weight). In non-smokers (investigators' design to subtract a major source of cadmium from tobacco smoke), this level is reached after 50 years of an oral daily intake of 1.0 µg/kg body weight. As such, a LOAEL of 1.0 µg/kg-day was established.

OEHHA (1999a) applied this LOAEL in conjunction with an aggregated uncertainty factor (UF) of 100 (10 for intra-human variability, 3 for LOAEL to NOAEL extrapolation, and 3 for uncertainty in applying adult biokinetics to the entire age range from infancy to adulthood) for calculating a safe dose of 0.01 µg/kg-day. A factor of 3

(rather than the usual default of 10) was used for extrapolating from a LOAEL to a NOAEL because the LOAEL was based on the minimal adverse effect observed. The safe dose in turn was used to derive the PHG.

Current Evaluation Results

Because the cadmium data have recently been reviewed under the PHG process, we used the PHG review as a baseline for the current evaluation. Accordingly, we focused our literature search and review on the information that was not covered by the PHG evaluation. An attempt was also made to target literature pertaining to cadmium's effect on sensitive organ systems that are still undergoing postnatal development.

Based on the above search criteria, we compiled a list of references. From that list, we identified a number of papers relevant to cadmium's effects on testes and semen of rabbits exposed before and after puberty (Foote, 1999); pubertal and postpubertal cadmium exposure on the hypothalamic-pituitary-testicular axis function in rat (Lafuente et al., 2000); cadmium induction of apoptosis in the immune system (Tsangaris et al., 1998); postnatal cadmium exposure and long-term behavioral changes in rat (Smith et al., 1982); effects of cadmium and lead on cognitive functioning in children (Thatcher et al., 1982); and neurotoxic effects of cadmium in young rats (Wong et al., 1982). However, these were either qualitative/mechanistic, semi-quantitative, or quantitative studies with a LOAEL higher than that on which the PHG was based.

Recommendation

The renal effect of cadmium seems to be the most sensitive endpoint (with the lowest LOAEL), even when it is compared with developmental and reproductive study endpoints identified in the OEHHA PHG document or those identified by OEHHA's current evaluation. The rate of cadmium absorption affects its rate of accumulation in the kidney, and in turn its toxicity. Thus, available data suggest the PHG LOAEL should be retained for our current consideration. This LOAEL is lower than the NOAEL used by U.S. EPA in developing its RfD. Both the safe dose from which the PHG was derived and U.S. EPA's RfD are based on cadmium's effect on renal function. In developing these two health criteria, long-term cumulative exposure data were used. Both U.S. EPA and Buchet et al. applied a 5 percent absorption in their respective biokinetic modeling, based on adult human absorption of 4.7 to 7 percent of the cadmium intake (Rahola et al., 1972, cited in Mahaffey, 1983). In proposing the PHG, OEHHA applied a factor of 3 to account for the uncertainty associated with Buchet's modeling in which he applied adult biokinetics to the entire age range from infancy to adulthood. According to Alexander et al. (1974), the absorption of cadmium by children, from early infancy through 8 years of age, averages 55 percent.

To illustrate the appropriateness for applying the factor of three for developing the chRD, OEHHA ran a model similar to Buchet, using his modeling assumptions. Using a daily dose of 1 µg/kg, an absorption rate of 5 percent, and a daily clearance rate of 0.005

percent of body burden, OEHHA estimated that the urine excretion of 2 µg cadmium /24 hour (LOAEL biomarker) would be reached by age 53, which was in good agreement with Buchet's study. However, by changing the absorption rate to 55 percent through age 8, then decreasing it linearly to 5 percent at age 21, while keeping the other parameters the same, a daily dose of 0.51 µg/kg would be required to produce an urine excretion of 2 µg cadmium /24 hour by age 53. Thus, using child-specific absorption results in a difference of about 2-fold in the daily dose to produce the LOAEL effect. To be public health protective, OEHHA proposes to apply a child-protective factor of 3 to account for childhood absorption differences.

Calculation of the non-cancer chRD for cadmium is based on the following equation:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF} \times \text{CP}} = \frac{1 \text{ } \mu\text{g/kg-day}}{30 \times 3} = 0.01 \text{ } \mu\text{g/kg-day}$$

Where,

LOAEL = Lowest-observed-adverse-effect-level from Buchet et al., 1990.

UF = Uncertainty factor of 30 (10 for intra-human variability, 3 for LOAEL to NOAEL extrapolation because the LOAEL is based on the minimal effect observed and this is consistent with that applied to calculate the PHG).

CP = Child protective factor of 3 to account for the GI absorption difference between children and adults.

Accordingly, OEHHA is proposing a chRD of 0.01 µg/kg-day for cadmium's non-cancer effect to be used in school-site risk assessment instead of the U.S. EPA's RfD that did not account for a greater GI absorption of cadmium by children.

2.2 Chlordane

Chlordane is a cyclodiene pesticide, one of many organochlorine insecticides. Chlordane was used in large quantities until the U.S. EPA issued a notice of suspension except for use on subterranean structural termite control in 1976 (McConnachie and Zahalsky, 1992). It was banned for all uses in the United States in 1988, but it is still manufactured for export. Like DDT, it persists in the environment, and it is considered a priority persistent, bioaccumulative toxic (PBT) chemical by U.S. EPA (U.S. EPA, 2002).

Chlordane is not a pure chemical pesticide, and all studies investigating its toxicity or mechanism of action have used technical grade chlordane, which is a mixture. Infante et al. (1978) analyzed technical chlordane and reported that it contained 38-48 percent cis- and trans-chlordane, 3-13 percent heptachlor, 5-11 percent nonachlor, 17-25 percent other chlordane isomers, and a small amount of other compounds. Dearth and Hites (1991) identified 147 different compounds in a preparation of technical chlordane that included cis-chlordane (15 percent), trans-chlordane (15 percent), trans-nonachlor (15 percent), and heptachlor (3.8 percent).

OEHHA included chlordane in the "Compilation of Chemicals Potentially Found at School Sites" because it has been targeted by federal and state agencies as a chemical that may present environmental health risks. Chlordane appears on all but one of the chemical compilations that OEHHA has selected to identify chemicals that may be found at school sites. These compilations include:

- Soil contaminants identified at potential school sites in environmental investigations reviewed by the Department of Toxic Substances Control
- Toxic Air Contaminants (TACs) in California identified by OEHHA
- Analytes in the Department of Health Services/Air Resources Board (DHS/ARB) Portable Classroom monitoring study
- Analytes in the U.S. EPA National Health Exposure Assessment Study (NHEXAS)

Chlordane was placed by OEHHA in the compilation of "Candidate Chemicals Based on Critical Health Effects" because 1) it is on the Proposition 65 Developmental and Reproductive Toxin List and 2) a survey of recent scientific literature indicated that it possesses toxicity to organ systems that are developing in children, including the immune system, neuroendocrine and female reproductive systems (Ahmed, 2000; Barone et al., 2000; Barnett et al., 1990; Blyler et al., 1994; Brucker-Davis, 1998; DeRosa et al., 1998; Holladay et al., 2000; Holladay, 1999; Luster et al., 1990; Olea et al., 1998; Reigart, 1995; Spyker-Cranmer et al., 1982; Theus et al., 1992a and 1992b; Voccia et al., 1999). Chlordane exposure has also been associated with childhood cancer (Zahm et al., 1998.)

OEHHA staff prepared a PHG for chlordane in 1997 (OEHHA, 1997). The study on which the PHG is based showed that chlordane acted as an endocrine disruptor and

altered sex steroid-mediated behaviors when exposure occurred during gestation and lactation (Cassidy et al., 1994).

Endocrine disruptors, such as chlordane, are the subject of recent scientific and regulatory concern (U.S. EPA, 1998). They mimic or antagonize estrogens, androgens, and thyroid hormones, as well as their antagonistic analogs, and consequently disrupt the processes or tissues these hormones affect. Organ systems responsive to the sex steroids include the male and female reproductive organs, the central nervous system, and the immune system. The thyroid hormones affect most tissues (Bigsby, 1999). They are of particular concern in regard to children's health because they may disrupt the action of estrogen, androgen and thyroid hormones during critical periods of development and lead to permanent alterations in the reproductive, nervous, and immune systems that are developing during prenatal growth and childhood (Bigsby, 1999).

Existing Health Guidance Values

U.S. EPA Carcinogen Slope Factor: 3.5×10^{-1} per mg/kg-day

Chlordane is classified as B2; probable human carcinogen, using the 1986 Guidelines for Carcinogen Risk Assessment (Integrated Risk Information System (IRIS), 2003, <http://www.epa.gov/iris/subst/0142.htm#carc>). IRIS also reports that "under the 1996 Proposed Guidelines, it would be characterized as a likely carcinogen by all routes of exposure. These characterizations are based on the following summaries of the evidence available: (1) human epidemiology studies showing non-Hodgkin's lymphoma in farmers exposed to chlordane and case reports of aplastic anemia; chlordane associated with home use are inadequate to demonstrate carcinogenicity; (2) animal studies in which benign and malignant liver tumors were induced in both sexes of four strains of mice and occurred with an elevated, but not statistically significant, incidence in a fifth strain, as well as liver toxicity but no tumors in rats of two strains; and (3) structural similarity to other rodent liver carcinogens." The U.S. EPA oral slope factor is 3.5×10^{-1} per mg/kg-day. This value represents the geometric mean for five data sets with a range from individual data sets of 1.1×10^{-1} to 8.6×10^{-1} using the linearized multistage model (<http://toxnet.nlm.nih.gov/>). The EPA IRIS data base reported that the studies are of good quality and "the confidence is high that chlordane is a mouse liver carcinogen at dietary concentrations above 10 ppm. Although there is indication that the dose-response curve is sublinear in the dose region between 5 and 60 ppm, linearity at low doses cannot be ruled out on theoretical grounds. The tentative evidence is that the hematopoietic system, rather than the liver, is the target organ in humans."

U.S. EPA RfD: 5×10^{-4} mg/kg-day

The oral RfD established by U.S. EPA is 5×10^{-4} mg/kg-day based on a NOAEL of 0.15 mg/kg-day and LOAEL of 0.75 mg/kg-day in a mouse study (Khasawinah and Grutsch, 1989). The critical effect for the LOAEL was liver necrosis, with an uncertainty factor of 300 (10 for interspecies extrapolation, 10 for human variability, and 3 for deficiencies in

the database). The overall confidence given this RfD assessment is medium, both for the quality of the principal study and the sufficiency of the database. The principal study, assigned a confidence of medium, is a rat chronic oral study performed with relatively large group sizes, in which histopathological analyses on the known animal target tissue, the liver, were thoroughly performed. However, the discussion in IRIS stated that "available occupational studies, although limited, give no indication that the liver is a target organ in humans as a consequence of chronic exposure to low levels of chlordane" (<http://www.epa.gov/iris/subst/0142.htm#umfinhal>).

IRIS also reports that "recent evidence indicates that neurotoxicity, a known human endpoint in acute exposures, may be a relevant endpoint in chronic human exposures, and no chronic animals studies have examined neurotoxicity. Studies on pre-and postnatal animals indicating chlordane mimicry of sex-steroids raise reproductive concerns and no multigenerational reproductive studies, by any route, exist. Thus, there is some concern that the appropriate endpoints have not been examined adequately in the existing database." IRIS further states that "an area of scientific uncertainty in this assessment concerns the role of neurotoxicity, and possibly hematotoxicity, in chronic chlordane toxicity in humans." IRIS also notes that "another area of scientific uncertainty in this assessment concerns the toxicological significance of endocrine mimicry effects of chlordane. Toxicity data for this chemical include a study demonstrating biochemical and behavioral alterations consistent with technical chlordane (or its metabolites) mimicking male sex-steroids (Cassidy et al., 1994). That these effects could include reproductive behaviors is suggested in this study" (<http://www.epa.gov/iris/subst/0142.htm#quaoral>).

Studies on these endpoints would be of concern for children's health because accidental poisoning studies by chlordane in children have reported neuropsychiatric symptoms, which included learning disabilities, at an incidence four times that found in the general population according to the National Center for Health Statistics (Sherman, 1999). In 20 poisoned children, 20 percent had hematological problems and an additional 15 percent had hematological dyscrasias which may be early indicators of leukemia and aplastic anemia (Sherman, 1999).

OEHHA PHG: 0.02 ppb (a safe dose of 1×10^{-5} mg/kg-day)

The PHG developed by OEHHA is 1×10^{-5} mg/kg-day, or 0.02 ppb in drinking water, based on a LOAEL of 0.1 mg/kg-day because of disruption of sex steroid-mediated behaviors in rat identified by Cassidy et al., 1994. The health-protective drinking water concentration for carcinogenic endpoints is calculated to be 0.03 ppb. The U.S. EPA drinking water unit risk is 1×10^{-5} per ($\mu\text{g/L}$) which translates into risk levels of 10^{-4} to 10^{-6} at concentrations of 3 ppb and 0.03 ppb, respectively (U.S. EPA, 1996).

Current Evaluation Results

Chlordane has been shown to have critical effects on two developing systems due to endocrine disruption. It adversely affects the developing immune system of mice (Spyker-Cranmer et al., 1982; Barnett et al., 1985a; Barnett et al., 1985b; Barnett et al.,

1990; Theus et al., 1992a; Theus et al., 1992b; Blyler et al., 1994), and it alters sex-mediated neurobehavioral endpoints (Cassidy et al., 1994). These effects on the developing endocrine and immune systems show an age-related susceptibility to chlordane. Adult animals exposed to similar or higher doses of chlordane did not show similar effects (Johnson et al., 1986; Barnett et al., 1990; Barnett, 1997).

An endocrine disruptor such as chlordane can act at the level of the hypothalamic-pituitary-adrenal (HPA) axis, disrupting the negative feedback loop between the brain and the immune system. Under normal physiological conditions, activation of the immune system stimulates the release of cytokines, which can then act on the HPA axis to trigger the release of corticosterone. However, if increased levels of corticosterone are released, due to the presence of endocrine disruptors, these high corticosterone levels produce immuno-suppression on virtually all levels of the immune system (Gaillard and Spinedi, 1998; Morale et al., 1995), including depression of the delayed-type hypersensitivity response (Okimura et al., 1986), suppression of granulocyte and macrophage migration (Mizobe et al., 1997), and inhibition of hematopoietic cytokines such as IL-3 and CFU-GM (Gaspar Elsas et al., 2000 and Mucha et al., 2000).

In addition, high levels of glucocorticoids can disrupt all aspects of the hypothalamic-pituitary-gonadal (HPG) axis, including reproductive behavior and the synthesis and release of sex steroids (Viau, 2002) and can interfere with the functioning of the hippocampus, the part of the brain responsible for learning and memory (Kim and Diamond, 2002). It has been shown that the release of adrenocorticotrophic hormone (a hormone that stimulates the release of corticosterone) is associated with increased sexual excitation in male rats (Szechtman et al., 1974), and Bowman and colleagues (2001) demonstrated that female rats exposed to stress-induced increases in corticosterone levels showed altered spatial memory performance.

A key finding, suggesting that chlordane disrupts the HPA and HPG axis, was the observation that exposure of the dihybrid mice dams to 0.16 mg/kg-day of analytical reference standard chlordane (which has the same products as technical grade chlordane) from 0-18 days of gestation (Table 2.2.1) produced significantly elevated corticosterone in male and female offspring when they were assayed as adults at 100 and 400 days of age (Cranmer et al., 1984). This indicated a permanent (or long-lasting) effect on the offspring. This dose of technical grade chlordane also reduced metabolism of corticosterone in female BALBc mice and elevated resting plasma corticosterone in male mice at 100 days of age (Spyker-Cranmer et al., 1982). Corticosterone, like cortisol, is synthesized from progesterone by a series of hydroxylations. Testosterone is also synthesized from progesterone, and estradiol is synthesized from testosterone (Stryer, 1981). Chlordane can alter corticosterone levels, and corticosterone is an intermediate in the synthesis of steroids. By this mechanism, chlordane can affect the developing immune system, and it could permanently alter characteristic differences between males and females in non-reproductive and reproductive measures (such as body weight, development of sexual organs, circulating steroid levels, mating behavior, spatial abilities, activity level, or mixed function oxidase levels (Weiss, 2002). The endocrine

disruptive effect of chlordane appears to be corroborated by the study of Cassidy and colleagues (Cassidy et al., 1994) in which a dose of 0.1 mg/kg-day chlordane to the dam and then to the pups until postnatal day 80 caused sex steroid-mediated changes in gender-specific behaviors and functions (Cassidy et al., 1994). There was a dose-responsive decrease in plasma testosterone, which was significant at 5 and 0.5 mg/kg-day, but not significant at 0.1 mg/kg-day.

Table 2.2.1 Summary of Significant Studies on Chlordane

Reference	Protocol	Doses	Critical Effects
Spyker-Cranmer et al., 1982	Pregnant BALB/C mice were dosed until day 18 of gestation and pups nursed on their natural mothers until 21 days of age	0.16 and 8 mg/kg maternal body weight	Delayed Type Hypersensitivity (DTH) was significantly depressed at 8 mg/kg; and depressed but not significantly at 0.16 mg/kg
Cranmer et al., 1984	Pregnant F2 Dihybrid mice were dosed until day 18 of gestation and pups nursed on their natural mothers until 21 days of age.	0.16 and 8 mg/kg maternal body weight	Plasma corticosterone was significantly elevated at 101 days and 400 days in male mice whose mothers were dosed with 0.16 mg/kg-day. It was elevated in female mice at 400 days of age
Barnett et al., 1990	Pregnant BALB/C mice were dosed until day 18 of gestation and pups nursed on their natural mothers until 21 days of age	4 and 8 mg/kg maternal body weight	Hematopoietic stem cells (CFU-GM and CFU-S) in offspring were significantly decreased at 100 and 200 days of age. Adult animals treated with 8 mg/kg chlordane did not have any decrease or differ from controls.
Cassidy et al., 1994	Sprague-Dawley CD rats were dosed from Day 4 of gestation until Day 21 of lactation. Pups were dosed individually from post natal day (PND) 22 until PND 80.	0.1, 0.5, and 5 mg/kg maternal body weight	Females had significant improvements in spatial abilities in the Cincinnati Water Maze test at all doses, males exhibited dose-dependent increases in male-typical mating behavior, and both exhibited maximum response to auditory startle at 0.1 mg/kg when tested at 80 days.

The effects of chlordane on the developing immune system, and their persistence into adulthood, were demonstrated in a series of related studies using prenatal and postnatal exposure to chlordane (Spyker-Cranmer et al., 1982; Barnett et al., 1985a; Barnett et al., 1985b; Barnett et al., 1990; Blyler et al., 1994; Theus et al., 1992a; Theus et al., 1992b). The experimental protocol common to all the studies was to feed pregnant mice 0.3 mg of peanut butter which was spiked with technical chlordane to provide a maternal dose of 0.16 mg/kg, 4 mg/kg, 8 mg/kg or 16 mg/kg maternal body weight, although not all doses were used in the assay of each immune system parameter. The pups were allowed to

nurse through day 21. Assays of immune system parameters were performed at various postnatal days, ranging from day 42 to day 200, although not each immune system parameter was assayed at each postnatal time point. Chlordane is fat-soluble, having a log K_{ow} (octanol-water coefficient) of 5.16, so it should be readily transferred from plasma to milk. The total amount of chlordane reaching the pups was determined to be 3.5 mg/kg by analyzing chlordane and its metabolites in the conceptus and in pups at intervals during gestation and through the end of lactation (Theus et al., 1992)

Immune responses, such as delayed type hypersensitivity (DTH), were significantly depressed in offspring at 100 days of age after exposure in utero to a maternal dose of 8 mg/kg-day body weight. A maternal dose of 0.16 mg/kg-day also depressed DTH, although not significantly (Spyker-Cranmer et al., 1982). Pups received chlordane from 0-18 days of gestation, when the mother was dosed, and through 21 days of nursing, when dosing of the mother had ceased. Thus, the pup's exposure dose was actually lower than either 8 mg/kg-day or 0.16 mg/kg-day for its exposure duration.

A decreased DTH response occurs due to functional abnormalities in T lymphocytes, specifically the CD4 T_H1 helper cells. There are three kinds of effector T cells: cytotoxic CD8 T cells, which kill infected cells, and two kinds of CD4 T cells (T_H1 , or T helper 1, and T_H2) with different functions (Parham, 2000). It is noteworthy that a decrease in the number of helper/inducer T cells is found in acquired immune deficiency (AIDS) disease, and this decrease is thought to allow infections such as Kaposi's sarcoma, Pneumocystis carinii pneumonia, and cytomegalovirus (CMV) retinitis (Lane and Fauci, 1985).

A critical effect on the developing immune system was a significant reduction in the number of granulocyte-monocyte committed stem cells (CFU-GM) and multipotential stem cells (CFU-S) in adult offspring (100 and 200 days of age) of pregnant mice exposed to 4 mg/kg and 8 mg/kg chlordane (Barnett et al., 1990). The bone marrow of offspring exposed to 4 or 8 mg/kg-day chlordane had 63 percent and 75 percent of control CFU-GM at 100 days of age, and at 50 percent and 77 percent at 200 days of age in offspring exposed to 4 mg/kg-day. The multipotential stem cells (CFU-S) were similarly depressed. Female and male offspring exposed prenatally to 8 mg/kg chlordane had 67 percent and 64 percent respectively of control CFU-S, while those exposed to 4 mg/kg-day chlordane had 78 percent and 87 percent of control CFU-S. At 200 days of age the bone marrow CFU-S in female offspring was almost unchanged, and that in males was still significantly reduced. This significant reduction in stem cells which could divide and differentiate into mature functional blood cells could produce life-threatening consequences. This decrease, as well a decrease in Interleukin-3 (IL-3) stem cells, was confirmed to be present at 42-49 postnatal days when specific recombinant growth factors were utilized (Blyler et al., 1994). IL-3 is a cytokine produced by T helper (T_H1 and T_H2) cells and it is a growth factor for multipotential progenitor hematopoietic cells (Parham, 2000). This toxicity endpoint is significant for humans because blood dyscrasias and bone marrow failures have been reported in people following accidental dermal or inhalation exposure to chlordane at unspecified dose levels (Infante et al., 1978; Klemmer et al., 1977; Furie and Trubowitz, 1976).

Clonogenic assays for hematopoietic progenitors have been used in clinical hematology for 30 years (Parent-Massin, 2001) and in research to predict adverse effects of drugs or toxicants, as the rapid rate of cell renewal and differentiation makes the hematopoietic system a susceptible target for xenobiotic toxicity. Xenobiotics that interfere with cell proliferation and differentiation can lead to “bone marrow failure.” The two major groups of bone marrow failure are aplastic anemia, where the failure lies in the pluripotent stem cell (colony forming unit – stem cell or CFU-S), and single cytopenia, where the failure lies in the stem cell for one of the committed cell lines, such as the granulocyte/monocyte cell line, the CFU-GM (Parent-Massin, 2001). Most bone marrow failures are characterized by inadequate production of blood cells and, if severe, death of the organism results because existing numbers of stem cells have an inadequate ability to produce mature cells to provide oxygen (anemia), clot blood (thrombocytopenia), or to protect the organism from infection.

Endocrine disruptors such as chlordane can affect neuroendocrine/neurobehavioral endpoints, as well as immune endpoints. The studies of Cassidy and colleagues (Cassidy et al., 1994) confirmed that perinatal chlordane could mimic sex steroids and /or change their levels to masculinize sexually dimorphic functions and behaviors. They dosed pregnant rats with technical chlordane at 0.1 mg/kg, 0.5 mg/kg, and 5 mg/kg during gestation, and they dosed the offspring during 21 days of lactation and from postnatal day 22 to postnatal day 80. Female offspring committed fewer errors than controls in three assays of cognitive and spatial ability in the Cincinnati Water Maze test, appearing to behave more like males, and male offspring exhibited dose-dependent increases in male-typical mating behaviors. The differences in behavior compared to unexposed animals demonstrate that sexual differentiation of the neuroendocrine system has been altered by early life exposure to chlordane. The neuroendocrine-gonadal axis regulates the developmental organization and adult expression of behaviors critical for mammalian survival and reproduction (competitive aggression, exploration, and sexual and parental behaviors), so neurobehavioral alterations induced by endocrine disruptors may impact the survival and fitness of an individual in its environment (Palanza et al., 2002)

Recommendation

Based on studies that describe endocrine disruption and effects on the developing hematopoietic, immune and neuroendocrine systems in young animals, OEHHA recommends that a chRD be developed. The critical effects are alterations in characteristic behavior differences between males and female at doses of 0.1 mg/kg-day maternal body weight and 0.1 mg/kg-day pup weight (Cassidy et al., 1994), and disruption of the hematopoietic and immune systems at a maternal dose as low as 0.16 mg/kg-day maternal body weight (Cranmer et al., 1984).

OEHHA recommends that a non-cancer child-specific RD be calculated on the study by Cassidy and colleagues (Cassidy et al., 1994) that showed that a chlordane dosage of 0.1 mg/kg-day (to the pups, as well as the mother) disrupted sex hormone mediated

behaviors. Differences from control were significant at the lowest dose, indicating that 0.1 mg/kg dose is a LOAEL. Because these effects are indicative of endocrine disruption, it is possible that the hematopoietic/immune effects described in the other studies may also occur at this low dose.

Calculation of the non-cancer child-specific RD for chlordane is based on the following equation:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF}} = \frac{0.1 \text{ mg/kg-day}}{3000} = 3.33 \times 10^{-5} \text{ mg/kg-day}$$

Where,

LOAEL = Lowest Observed Adverse Effect Level (Cassidy et al, 1994)

UF = Uncertainty factors of 3000 (10 for LOAEL to NOAEL, 10 for interspecies extrapolation, 10 for human variability, and 3 for inadequate database for hematotoxicity, immunotoxicity, neurotoxicity, and the lack of a valid developmental study).

Accordingly, OEHHA is proposing a non-cancer chRD of 3.3×10^{-5} mg/kg-day for chlordane.

Uncertainty and Modifying Factors

OEHHA has applied the additional uncertainty factor 3 for inadequacies in the database for each of three endpoints, hematotoxicity, neurotoxicity, and reproductive toxicity that data suggest may be of concern to human children. This uncertainty factor has been applied in accordance with U.S. EPA (1994) and Renwick et al., (2000), that it is appropriate "if a valid developmental toxicity study was not performed", or "if the study did not examine all developmental endpoints". In the discussion of chlordane on the IRIS database, U.S. EPA noted that "studies on pre- and postnatal animals indicating chlordane mimicry of sex steroids raise reproductive concerns and no multigenerational reproductive studies, by any route, exist. Thus, there is some concern that the appropriate endpoints have not been examined adequately in the existing database" (<http://www.epa.gov/iris/subst/0142.htm#umfinhal>).

The U.S. EPA RfD was based on hepatic necrosis in mice, even though the discussion on the IRIS database noted that "occupational studies, although limited, give no indication that the liver is a target organ in humans as a consequence of chronic exposure to low levels of chlordane." U.S. EPA reduced confidence in their RfD noting that "an area of scientific uncertainty concerns the role of neurotoxicity and possibly hematotoxicity in chronic chlordane toxicity in humans" (<http://www.epa.gov/iris/subst/0142.htm#umfinhal>). Neurotoxicity and hematotoxicity

have been reported as principal endpoints of acute chlordane toxicity in both experimentally poisoned animals and accidentally poisoned humans (Grutsch and Khasawinah, 1991; Fleming and Timmeny, 1993). The uncertainty increases when considering exposure of children, rather than adults, because these organ systems are undergoing critical development during childhood.

The reduced numbers of hematopoietic stem cells in offspring, after they had reached maturity, from exposure to a 4 mg/kg-day maternal dose (Barnett et al., 1990a), provides low confidence that a LOAEL which produced minimally significant adverse hematological effects was identified. Immune system toxicity from chlordane is a concern because a report of outcomes from exposure of 20 children to chlordane from pesticide applications noted that 20 percent had hematological problems and an additional 15 percent had hematological dyscrasias (Sherman, 1999). Blood cell dyscrasias are a concern to clinicians because they may later manifest themselves as leukemias and aplastic anemias. The outcome of reduced numbers of stem cells can be bone marrow failure.

The database on chlordane toxicity to children is also considered inadequate because no animal studies have adequately assayed neurotoxicity due to low chlordane exposure concentrations, and there are case reports of human neurotoxicity (Kilburn and Thornton, 1995; Kilburn, 1997). Al-Hachim and Al-Baker (1973) reported that when pregnant mice were exposed to 1 mg/kg-day technical chlordane for only seven consecutive days the pups had poor learning ability or altered motivation in the assay for conditioned avoidance response, raised seizure threshold, and increased exploratory activity. Reports of accidental human exposure to termiticides have resulted in neurobehavioral impairments in adults (Kilburn and Thornton, 1995; Kilburn, 1997) and 70 percent of 20 child patients exposed to chlordane had neuropsychiatric symptoms, which included learning disabilities at an incidence four times that found in the general population, according to the National Center for Health Statistics (Sherman, 1999). School-age children were reported to develop new problems: headaches, visual difficulties, hyperactivity, learning disabilities, frequent ear-nose-throat and chest problems, and gastrointestinal disturbances (Sherman, 1999).

The Food Quality Protection Act required a 10 fold safety factor be applied "for infants and children" for pesticide risk assessments "to take into account...completeness of the data with respect to ... toxicity" and OEHHA utilized the 10 fold factor in creating a public health goal (PHG) for chlordane. However, U.S. EPA has been limiting the composite factor to 3,000 when human-equivalent doses are used (U.S. EPA, 1994). As the low dose in the Cassidy et al. (1994) study, which forms the basis for the child-specific RfD, was based on serum levels found in the United States at the 99th percentile (i.e. 1% of the U.S. values are higher), OEHHA decided to utilize only a 3-fold modifying factor to account for the inadequacies in the database.

Additional Comments/Studies:

The experiments from Barnett and colleagues (Spyker-Cranmer et al., 1982; Barnett et al., 1985a; Barnett et al., 1985b; Barnett et al., 1990; Theus et al., 1992a; Theus et al., 1992b; Blyler et al., 1994) support an equivalent or lower dose than the one derived from the Cassidy et al., 1994 study. The experimental protocol of Barnett and colleagues differed from that of Cassidy et al., 1994, in that the pup was not individually dosed. A maternal dose of 8 mg/kg-day was reported to produce a *total* dose of 3.5 mg/kg of chlordane in the pup (Theus et al., 1992). If an equal fraction of 3.5 mg/kg dose were delivered each day of the 18 days of gestation, when the mother was dosed, and the 21 days of lactation, when the mother was not dosed, the pup would receive 0.09 mg/kg-day over the 39 day period. This estimated pup dose is very close to the 0.1 mg/kg-day dose that Cassidy et al. (1994) gave to dams, *and* to pups following weaning and until sacrifice on day 80.

The experiment of Cranmer et al. (1984) suggests that the LOAEL could be lower than 0.1 mg/kg-day. In this study, the dams were dosed with either 0.16 mg/kg-day or 8 mg/kg-day chlordane during gestation. As noted above, the maternal dose of 8/mg/kg-day was shown to produce a total dose of 3.5 mg/kg in the pups when the concentration of chlordane metabolites analyzed on successive days during the 39 days of gestation and lactation were totaled. The average daily dose to the pup was 0.09 mg/kg-day. If the toxicokinetics from the 0.16 mg/kg-day maternal dose is proportional to that from the 8 mg/kg-day maternal dose, then the pups of a dam dosed with 0.16 mg/kg-day (Cranmer et al., 1984) would receive 0.0018 mg/kg-day. Emerging understanding of the hypothalamic-pituitary-adrenal (HPA) axis substantiates the possibility that a low dose may impair the developing immune system.

2.3 Heptachlor/Heptachlor Epoxide

Heptachlor (heptachlorodicyclopentadiene) was used primarily as an agricultural insecticide from 1952 to 1976, as a narcissus bulb and seed treatment and insecticide for fire ant control on pineapple crops until 1976, and as a treatment for subterranean termites until 1987 (Fendick et al., 1990). In 1985, heptachlor alone or in combination with chlordane, accounted for 60-65 percent of the termiticides used in the U.S. (EPA 1987 – see Fendick et al.). In 1987, the EPA and the Agency for Toxic Substances and Disease Registry (ATSDR) classified heptachlor as a priority Group 1 Hazardous Substance, making Superfund money available for cleanup of heptachlor-contaminated sites.

Technical heptachlor contains heptachlor plus related reaction products in approximately a 5:2 ratio (Fendick et al., 1990). Heptachlor is a moderately persistent compound (Ware et al., 1990). In the soil it undergoes multiple transformation and degradation reactions by at least three pathways: epoxidation, hydrolysis, and dechlorination. Epoxidation generates the more persistent and bioaccumulative metabolite, heptachlor epoxide, while hydrolysis is a detoxification reaction (Fendick et al., 1990). U.S. EPA has considered heptachlor and heptachlor epoxide two separate chemicals, and it has established separate RfDs, probably because heptachlor epoxide absorbs strongly to soil and is extremely resistant to biodegradation (Hazardous Substances Databank, <http://toxnet.nlm.gov>), persisting in soils for a long time (Ware, 1988).

OEHHA included heptachlor/heptachlor epoxide in the “Compilation of Chemicals Potentially Found at School Sites” because it has been targeted by federal and state agencies as a chemical that may present environmental health risks. Heptachlor appears on all but two of the chemical compilations that OEHHA has selected to identify chemicals that may be found at school sites. These compilations include:

- Soil contaminants identified at potential school sites in environmental investigations reviewed by the Department of Toxic Substances Control
- Toxic Air Contaminants (TACs) in California identified by OEHHA
- Analytes in the U.S. EPA National Health Exposure Assessment Study (NHEXAS)

OEHHA also included heptachlor/heptachlor epoxide in the compilation of “Candidate Chemicals Based on Critical Health Effects” because heptachlor epoxide is on the Proposition 65 Developmental and Reproductive Toxicant List, and a survey of recent scientific literature indicated that heptachlor and heptachlor epoxide are toxic to organ systems that are developing in children. These organ systems are the immune, nervous, endocrine, and male and female reproductive systems (Brucker-Davis, 1998; DeRosa et al., 1998; Moser et al., 2001; Nicolopoulou-Stamati et al., 2001; Rani et al., 1995; Smialowicz et al., 2001; Voccia et al., 1999). Heptachlor and heptachlor epoxide were also reported to produce cancer (Zahm et al., 1998 and <http://toxnet.nlm.nih.gov>).

Existing Health Guidance Values

U.S. EPA Carcinogen Slope Factor: 4.5 per mg/kg-day

Heptachlor is classified by EPA as a B2, probable human carcinogen, based on several studies. Davis (1965) fed groups of 100 male and 100 female C3H mice diets with 0 or 10 ppm heptachlor (purity not specified) for 2 years. Survival was low, with 50 percent of the controls and 30 percent of the treated mice surviving until the end of the experiment. A two-fold increase in benign liver lesions over the controls was reported. After a histologic reevaluation, Reuber (as cited in Epstein, 1976), as well as four other pathologists, remarked a statistically significant increase in liver carcinomas in the treated male (64/87) and female (57/78) groups by comparison to controls (22/73 and 2/53 for males and females, respectively). The NCI (1977) reported a significant dose-related increase of hepatocellular carcinomas in male and female B6C3F1 mice.

U.S. EPA RfD: 5×10^{-4} mg/kg-day

The current oral RfD for heptachlor given by U.S. EPA in 1991 is 5×10^{-4} mg/kg-day (<http://toxnet.nlm.nih.gov>). This value was derived from a three ppm dietary NOAEL in a two-year rat feeding study where the critical effect was liver weight increase (Velsicol Chemical, 1955, cited by U.S. EPA <http://toxnet.nlm.nih.gov/>). The LOAEL in this study was 5 ppm or 0.25 mg/kg-day and an uncertainty factor of 300 was employed. EPA reports that there is low confidence that this RfD is accurate because the principal study is of low quality; the database on chronic toxicity is incomplete. There are no teratology, reproductive, or studies in young animals.

An RfD for heptachlor epoxide was based on a study in which adolescent dogs were fed heptachlor epoxide for 60 weeks (Dow Chemical Company, 1954). The LOAEL of 0.5 ppm (0.0125 mg/kg-day) was based on an increased liver-to-body weight ratio in both males and females as a critical effect (Dow Chemical Co., 1958, cited in U.S. EPA IRIS online file, <http://toxnet.nlm.nih.gov/>). An uncertainty factor of 1000 was employed. EPA indicates there is low confidence that the RfD is accurate because the principal study is of low quality, and the chronic toxicity studies are of low quality. There were no rat or rabbit teratology studies.

OEHHA PHG: 8 ppt (a safe dose of 1×10^{-4} mg/kg-day)

OEHHA staff prepared a Public Health Goal (PHG) for heptachlor of 8×10^{-6} mg/L drinking water, based on a cancer slope factor of $4.1 \text{ mg/kg-day}^{-1}$ and a 1×10^{-6} cancer risk (OEHHA, 1999b). Heptachlor exposure produced a dose-related increase in the incidence of hepatocellular carcinoma in male and female B6C3F1 mice (NCI, 1977) and hepatocellular carcinoma in male and female C3H mice (Davis, 1965).

OEHHA (1999) considered two studies when non-cancer effects were reviewed. The first was the two-year rat feeding study where the critical effect was liver weight increase that was used by EPA when it last revised the heptachlor RfD (Velsicol Chemical, 1955, cited by U.S. EPA, <http://toxnet.nlm.nih.gov>). Uncertainty factors of 10 for interspecies variability and 10 for interindividual variability were used. The second study (Cassidy et al., 1994) reflected the recent concern about the endocrine disruption effects of chlorinated cyclodiene and other chlorinated pesticides. The critical effect in this study was the alteration of sex steroid-mediated behaviors by prenatal and early-in-life exposure to 0.1mg/kg/day technical chlordane which contains 10percent heptachlor. In this calculation, the uncertainty factors are: LOAEL to NOAEL extrapolation (10), interspecies variability (10), and interindividual variability (10), resulting in a "safe" non-cancer human dose of 1×10^{-4} mg/kg/day

Current Evaluation Results

The effects of heptachlor that are specific for children are its disturbance of the development of the endocrine system and of the organs that respond to endocrine signals when exposure occurs during prenatal and/or early postnatal life (Colborn, 1993). These effects are permanent.

Contamination of the commercial milk supply of Oahu, Hawaii, with heptachlor for 15 months, from 1981 to 1982, and the subsequent finding of heptachlor epoxide in human milk, prompted new studies on rats to look for possible effects of heptachlor and its persistent primary metabolite at the concentrations to which children were exposed. The Hawaii Heptachlor Research and Education Foundation (HHREF) cosponsored these studies with the U.S. EPA and NIEHS in order to evaluate many aspects of the impact of heptachlor exposure during the perinatal/juvenile period of development, using a broad battery of tests of immune and reproductive system function.

The doses (0, 0.3, 3, or 30 mg/kg-day of 99% pure heptachlor) employed were adjusted so that the low dose gave milk values of heptachlor epoxide that approximated the 95th percentile of human milk heptachlor and heptachlor epoxide values in Oahu, Hawaii in 1981 (Baker et al., 1991; Siegel, 1988 in Smialowicz et al., 2001). The period of exposure was designed to approximate the last trimester of pregnancy through 18 years of age in humans. The experimental design for the studies of endocrine disrupting effects on immune, neurobehavioral, and reproductive is given in Figure 2.3.1.

Figure 2.3.1 Experimental Design

Figure taken from Moser et al., 2001 and Smialowicz et al., 2001)

The results of one subset of this study (Smialowicz et al., 2001) indicated that exposure of rats to heptachlor during the last trimester of gestation through puberty adversely affects adult functioning of the immune system by suppressing the primary IgM and secondary IgG antibody response in male offspring. Rats were exposed to 0, 0.3, 3, or 30 mg/kg-day from gestation day 12 to postnatal day 7, followed by direct dosing through postnatal day 42. The LOAEL was identified as 0.3 mg/kg-day because the primary IgM antibody response to Sheep Red Blood Cells (SRBCs), as measured by enzyme linked immunosorbent assay (ELISA) was suppressed at 8 weeks of age and at 21 weeks of age. At the same dose, the secondary IgG response was also suppressed at 25 weeks of age. These responses require three major immune cell types: macrophages, the CD4+ T-helper cells, and B cells. Alterations in or dysfunction of any of these cells and cell interactions can result in aberrant antibody production (Luster et al., 1988 in Smialowicz, 2001). The suppression of these T cell-dependent antibody responses persisted through the first six months of life at all doses employed, including the lowest dose, 0.3 mg/kg-day, which was administered through 6 weeks of age.

The response to SRBC is one of the most sensitive functional parameters in animals exposed to immunosuppressants (Luster et al., 1992). Consequently, it is included in the battery of tests required by the Federal Insecticide, Fungicide, and Rodenticide (FIFRA) guidelines for detection of immunosuppressants (Smialowicz, 2001). In both animals and humans, T-cell dependent responses are involved in protection against viral, bacterial, and parasitic infections (Blanden, 1974 in Smialowicz, 2001). Consequently, the suppression of the primary IgM and secondary IgG antibody responses suggests potential increased susceptibility to infectious diseases.

In another subset of rats from the same large study, heptachlor produced significant differences in tests for cognitive abilities that are associated with the development of neuroendocrine pathways (Moser et al., 2001). Rats were evaluated for neurological and behavioral alterations using a functional observational battery (FOB), an automated measure of motor activity, passive avoidance, and a Morris water maze test (Moser et al., 2001). Rats dosed prenatally and postnatally until day 21 had changes in activity measures, but those in which dosing continued until day 42 had alterations in autonomic, neuromuscular, and excitability measures. The most pronounced effects of heptachlor occurred in rats treated until day 42 and tested with the Morris water maze test. The Morris water maze test (Morris, 1984) was devised to resolve theoretical controversies about the basis of spatial and working memory. Normal rats learn very quickly to swim directly towards a platform from any starting position at the circumference of a pool. The accurate directionality of their escape behavior provide evidence that the rats escape by learning the position of the platform relative to distal cues. Thus, their performance can be compared to those of animals exposed to potential neurotoxins to assay spatial learning and memory (Morris, 1984).

Heptachlor exposure slowed acquisition of the spatial task and impaired recall during probe trials: the treated male rats at all dose levels did random searching for the platform, rather than developing an efficient search strategy. Working memory, which was assayed by requiring the rats to learn a new position for the platform each day, was significantly decreased in the low dose (0.03 mg/kg-day) male rats which had been dosed with heptachlor prenatally and postnatally until Day 21. The escape latency (mean time to find the new location) was 27.9 seconds compared to 20.5 seconds in control (Smialowicz, et al., 2001).

Cyclodiene pesticides bind to the chloride channel portion of the receptor for the neurotransmitter gamma aminobutyric acid (GABA)_A, block the inhibitory actions of and thus affect a variety of neurological functions in both adult and young animals (Abalis et al., 1986; Cole and Casida, 1986; Gant et al., 1987 in Moser, 2001). Acute actions of cyclodiene pesticides include excitation, hyperstimulation, and convulsions (Cole and Casida, 1986; Fendick et al., 1990). In young mammals, the development of the nervous system is quite protracted, and specific processes of migration, proliferation, and differentiation occur from gestation throughout childhood and into adolescence. These processes occur in sequence, so disturbance of earlier processes can disrupt later developmental events. Cyclodiene insecticides alter expression of the GABA_A receptor. Since the neurotransmitter, GABA, influences development of serotonergic, dopaminergic, and cholinergic neurotransmitter systems, cyclodiene pesticides may produce long-lasting alterations in brain function (Lauder et al., 1998 in Smialowicz et al., 2001).

Recommendation

Heptachlor:

The experiments of Smialowicz et al. (2001) and Moser et al. (2001) describe several critical effects in young male rats at a LOAEL of 0.03 mg/kg-day heptachlor during the last half of gestation and the first 21 or 42 postnatal days. The most significant effects include suppression of the primary IgM and secondary IgG antibody response (Smialowicz et al., 2001), and decreased performance on measures of cognitive function, such as impaired recall (Moser et al., 2001).

Technical grade heptachlor and chlordane are mixtures of pure compound plus related reaction products (Ware, 1990). The PHG developed by OEHHA in 1999 utilized a study (Cassidy et al., 1994) that described a disruption of sex-steroid mediated behaviors in female mice at a dose of 0.01 mg/kg-day of technical grade chlordane, which contains 10 percent heptachlor. More recent studies (Smialowicz et al., 2001, Moser et al., 2001), which used heptachlor of 99 percent purity, have allowed OEHHA staff to develop the chRD for heptachlor without the ambiguity associated with testing a mixture.

Calculation of the non-cancer chRD is based on the following equation:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF}} = \frac{0.03 \text{ mg/kg-day}}{1000} = 3.0 \times 10^{-5} \text{ mg/kg-day}$$

Where,

LOAEL = Lowest Observed Adverse Effect Level from Smialowicz et al., 2001 and Moser et al., 2001

UF = Uncertainty factor of 1000 (10 for LOAEL to NOAEL, 10 for inter-species extrapolation, 10 for human variability)

Accordingly, OEHHA is proposing a non-cancer chRD of 3.0×10^{-5} mg/kg-day for heptachlor.

Heptachlor Epoxide:

Heptachlor has not been used since 1987 when its use was restricted. Heptachlor in the soil undergoes multiple transformation and degradation reactions, and epoxidation generates the more persistent and bioaccumulative metabolite, heptachlor epoxide (Fendick et al., 1990), so children at school sites may be exposed to heptachlor epoxide.

The principal study used by U.S. EPA to calculate an RfD (<http://toxnet.nlm.nih.gov>) was a 60-week dog feeding study (Dow Chemical Co., 1958) in which the LOAEL was an increased liver-to-body weight ratio. Although liver-to-body weight ratio is not a child-

specific endpoint, the exposure period began in adolescence and continued into young adulthood.

Since adolescent animals were exposed, OEHHA has decided to utilize the same study and the same uncertainty factors to calculate a non-cancer child-specific RD as the U.S. EPA RfD:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF}} = \frac{0.0125 \text{ mg/kg-day}}{1000} = 1.3 \times 10^{-5} \text{ mg/kg-day}$$

Where,

LOAEL = Lowest Observed Adverse Effect Level from Dow Chemical Co, 1958

UF = Uncertainty factor of 1000 (10 for LOAEL to NOAEL, 10 for inter-species extrapolation, 10 for human variability)

Accordingly, OEHHA is proposing a non-cancer chRD of 1.3×10^{-5} mg/kg-day for heptachlor epoxide.

2.4 Methoxychlor

Methoxychlor, 2,2-bis(p-methoxyphenyl)-1,1,1-trichloroethane, is structurally related to DDT. Because of its lower toxicity and bioaccumulation potential, methoxychlor became an attractive replacement of DDT (ATSDR, 1994). It was registered as an insecticide against a wide range of pests, including houseflies, mosquitoes, cockroaches, and various arthropods commonly found on fields crops, vegetables, fruits, stored grain, livestock, and domestic pets.

While DTSC's school site review efforts continue, methoxychlor has already been detected at a school site. Recent studies show that demethylated metabolites of methoxychlor are an endocrine disruptor. Accordingly, OEHHA believes it is important to further review methoxychlor pursuant to Health and Safety Code Section 901(g). As endocrine disruptors, methoxychlor metabolites may have adverse effects on different developing organ systems. These chemicals may disrupt the development and functioning of the female reproductive system, and the brain, and the male reproductive system (vom Saal et al., 1983, 1997; Nonneman et al., 1992; Hess et al., 1997). As such, the effect of methoxychlor or its metabolites could affect the development of school children. Moreover, earlier studies may have inadequately characterized the dose-response relationship of methoxychlor (NTP, 2001). In reviewing environmental estrogens, the NTP Peer Review Subpanel found that overall the classic estrogenic activity of methoxychlor was limited to doses greater than 5 mg/kg-day because testing at lower doses had not been incorporated into the experimental design. An updated review of the pertinent literature is necessary to ensure that the appropriate LOAEL or NOAEL will be considered in setting a child-specific guidance value.

Pertinent Guidance Values

U.S. EPA RfD: 0.005 mg/kg-day

U.S. EPA used the 1986 Kincaid Enterprises, Inc. study to establish its RfD. Young adult female New Zealand White rabbits were assigned into 3 dose groups of 17 animals each, 5.01, 35.5, and 251.0 mg/kg-day, and a control group (a total of 68 animals). The females were artificially inseminated and the day of insemination considered as gestation day 0. All animals were dosed from days 7 through 19 of gestation. All surviving dams were sacrificed on gestation day 29.

Maternal toxicity was observed as excessive loss of litters (abortions) and statistically significant decreases in body weight in the mid- and high-dose groups, and the deaths in the high dose group. No specific toxicity was noted in the low dose (5.01 mg/kg-day), which was deemed to be the NOAEL.

An uncertainty factor of 1000 was applied to the NOAEL in developing the RfD; of which 100 was used to account for the inter- and intra-species differences and an

additional 10 was used to account for the poor quality of the critical study and for the incomplete database on chronic toxicity.

OEHHA PHG: 0.03 mg/L (a safe dose of 0.005 mg/kg-day)

In reviewing literature for the purpose of establishing a Public Health Goal (PHG) for methoxychlor in drinking water (OEHHA, 1999c), OEHHA found the chemical to be negative in several mutagenicity tests. However, a positive test was reported for the induction of forward mutations in the mouse lymphoma assay. Large doses of methoxychlor decreased locomotor activity and caused tremors. Reproductive effects have been caused by the estrogenic activity of the o-demethylated metabolites of methoxychlor. These metabolites also bind estrogen receptors in animal and human tissues.

OEHHA identified the investigation by Chapin et al. (1997) as the most relevant study for use in developing a PHG for methoxychlor in drinking water. The investigation focused on effects of perinatal methoxychlor exposure on adult rats' nervous, immune, and reproductive system function. Dams were dosed orally at gestation day 14 through postnatal day (pnd) 7 and then pups were directly dosed at pnd 7 through pnd 42 at dosages of 0, 5, 50, and 150 mg/kg-day. Critical effects included a reduction in serum FSH, ovary weight and uterine weight at all dosages. The findings suggested that methoxychlor, as an exogenous estrogenic agent, had interfered with the normal programming of the ovarian-pituitary axis.

Applying the LOAEL of 5 mg/kg/day and an uncertainty factor of 1000 (10 each for inter-species extrapolation, intra-human variability, and LOAEL to NOAEL extrapolation), OEHHA calculated a safe dose of 0.005 mg/kg-day. This in turn was used to derive a PHG of 0.03 mg/L.

Current Evaluation Results

Stoker et al. (1999) investigated the effect of perinatal exposure of methoxychlor on the prostate of adult rat. The study showed that a perinatal dose of 50 mg/kg methoxychlor to the dam only from gestation day 18 to postnatal day 5 resulted in offspring with increased lateral prostate weight and inflammation at 90 days of age.

Welshons et al. (1999) reported increases in adult prostate size in mice from fetal exposure to methoxychlor. Females were dosed from day 11 to day 17 of pregnancy at 20 or 2000 µg/kg maternal body weight per day. Pups were weaned on postnatal day 23. When males reached 8.5 months old (adult), a randomly selected male from each litter was individually housed for 4 weeks to eliminate any effects of having been housed with other males before the selected male was sacrificed for various examinations. Prostatic weights were significantly increased in the 20 and 2000 µg/kg groups.

Table 2.4.1 Effects of Methoxychlor on Prostate Weight

	Prostate (mg)
Control	40.0+3.0
Methoxychlor (20 µg/kg)	64.5+3.7
Methoxychlor (2000 µg/kg)	60.3+4.1

The finding is not surprising as the prostate contains both androgen and estrogen receptors (Kumar et al., 1995) and it has been observed that estrogen can stimulate the growth of the stromal compartment of the prostate (Ekman, 2000). The study also illustrates the irreversible impact of endocrine disruptors during development.

vom Saal et al. (1995) discussed evidence that during fetal life, hormones have marked effects on subsequent behaviors. Male mice are particularly active in urine-marking behavior to indicate their social status. Urine marking was used as the end point to measure the effect of methoxychlor. Females received 0, 1, 10, 100, 1000, or 5000 µg/d from day 11 to day 17 of pregnancy. Two males from each litter were randomly selected when they were 60 days old and housed individually for four weeks to eliminate any effects of having been housed with other males. Urine-marking tests were conducted for one hour in clean cages with the floor lined by a sheet of Whatman No. 2 filter paper. The filter paper was then removed and discrete urine marks (which fluoresce under UV light) deposited on it were counted. The lowest dose (1 µg/day or 20 µg/kg-day based on 0.05 kg maternal weight) of methoxychlor significantly increased urine-marking behavior in male offspring.

Recommendation

OEHHA recommends that a chRD for methoxychlor be developed based on the data from Welshons et al. (1999) and vom Saal et al. (1995). While the exposure period used to demonstrate the significant effect on the prostate or neurobehavior was in the fetal period, OEHHA feels that both the prostate and neurobehavioral data (territorial marking) are applicable for school age children. The human prostate development is biphasic, with much of the growth occurring at puberty. It is small (weighs about 2 g) in childhood and undergoes exponential growth to about 20 g at puberty (Hayward et al., 2000). On the other hand, the process of brain development and maturation continues into adolescence (Rice et al., 2000). These systems remain vulnerable during the K-12 schooling period. Therefore, the Welshons and vom Saal data are an appropriate basis for evaluating hazards at schools.

OEHHA has also considered the appropriateness of using the maternal dose to calculate the chRD. OEHHA finds that methoxychlor crosses the placenta and partitions into the

lipids of milk (OEHHA, 1999). It is likely that the corresponding pup dose is higher on a per kilogram body weight basis. However, the demethylated (phenolic) metabolites rather than methoxychlor were shown to be the active species that displayed the endocrine disruption potential. The polar metabolites would not cross the placenta effectively. Additionally, methoxychlor that crosses the placenta would not be metabolized effectively by the pup whose P-450 enzymes are not fully developed. Thus, it would not be too conservative to use the maternal dose in this case to calculate the chRD.

Calculation of the non-cancer chRD for methoxychlor is based on the following equation:

$$\text{chRD} = \frac{\text{LOAEL}}{\text{UF}} = \frac{20 \mu\text{g/kg-day}}{1000} = 0.02 \mu\text{g/kg-day}$$

Where,

LOAEL= Lowest-observed-adverse-effect-level based on Welshons et al. (1999) and vom Saal et al. (1995)

UF= Uncertainty factor of 1000 (10 for inter-species extrapolation, 10 for intra-human variability, and 10 for LOAEL to NOAEL extrapolation)

Accordingly, OEHHA is proposing a non-cancer chRD of 0.02 $\mu\text{g/kg-day}$ for methoxychlor to be used in school-site risk assessment.

2.5 Nickel

Nickel, an important industrial metal, comprises 0.008 percent of the earth's crust (Duke, 1980 as cited in ATSDR, 1997). The production, use, and disposal of nickel have led to its mobilization in the environment and human exposure. Nickel is used in aircraft frames, jet engines, gas turbines, and turbosuperchargers, boats, hulls, propellers, and pumps (OEHHA, 2001). Nickel alloys are used in pumps and pipes to resist corrosion in petro-chemical industries. In addition, nickel is used in making coins and jewelry; as catalysts; and in magnets, batteries, and color pigment. Nationwide in 2000, 651,000 pounds of nickel were emitted into the air (with nickel plating operations as a major source of emission), 30,000 pounds were discharged into surface water, 17,000 pounds were injected underground, 2,032,000 pounds were disposed of onsite, and 8,700,000 pounds were disposed of offsite (U.S. EPA, TRI2000).

Nickel was selected for further evaluation pursuant to Health and Safety Code Section 901(g) because it meets both criteria for selection identified in OEHHA's 2002 report (OEHHA, 2002):

- DTSC reported the presence of nickel at two percent of the potential school sites evaluated to date. ARB reported its occurrence in California air (OEHHA, 2002). In addition, U.S. EPA and ARB/DHS have deemed nickel as a chemical of interest in their NHEXAS and Portable Classroom Study, respectively.
- OEHHA (2001) found a number of studies concerning the reproductive effects of nickel compounds. Nickel also adversely affected the immune functions in animals. The administration of nickel to rats increased the concentration of the metal in the hypothalamus and pituitary and inhibited prolactin secretion.

Pertinent Guidance Values

U.S. EPA RfD: 0.02 mg/kg-day

U.S. EPA's RfD is based primarily on the results of a two-year feeding study using rats given 0, 100, 1000 or 2500 ppm nickel (estimated as 0, 5, 50 and 125 mg Ni/kg bw) in the diet (Ambrose et al. 1976). In the 1000 and 2500 ppm groups (50 and 125 mg Ni/kg bw, respectively) body weights were significantly decreased compared with controls and the females had significantly higher heart-to-body weight ratios and lower liver-to-body weight ratios than controls. Since no significant effects were reported at 100 ppm (5 mg Ni/kg bw), this dose was a NOAEL. In this study, two-year survival was poor, particularly in control rats of both sexes (44 of 50 died), raising some concern about the interpretation of the results of this study. A subchronic study conducted by American Biogenics Corp. (ABC, 1986) also found 5 mg/kg-day to be a NOAEL, which supported the Ambrose et al. (1976) chronic NOAEL of 5 mg/kg-day.

An uncertainty factor (UF) of 300 (10 for interspecies extrapolation, 10 to protect sensitive populations, and 3 to account for inadequacies in the reproductive studies) was applied to the NOAEL of 5 mg/kg-day to compute an RfD of 0.02 mg/kg-day.

OEHHA PHG: 11.8 µg/L (a safe dose of 1.1×10^{-3} mg/kg-day)

OEHHA (2001) established a Public Health Goal (PHG) for nickel in drinking water that is based on three reproductive studies in rats (Smith et al., 1993; Springborn Laboratories, 2000a, b). In the Smith study 61-64 day old female rats (at puberty) were dosed at 0, 1.3, 6.8, or 31.6 mg/kg-day for 11 weeks prior to mating and then continuously during two sequential gestation and lactation periods. Breeder males were unexposed. The proportion of dead pups per litter was significantly increased in the 31.6 mg/kg-day group in both breedings and also in the 1.3 mg/kg-day group in the second breeding. Thus, 1.3 mg/kg-day was considered the LOAEL for this study.

The first Springborn report (Springborn Laboratories, 2000a) summarized a one-generation reproduction range-finding study in rats. 102 day-old animals (at sexual maturity) were dosed at 0, 10, 20, 30, 50, or 75 mg nickel sulfate hexahydrate/kg-day for two weeks prior to mating. OEHHA observed significant pup mortality at the lowest dose (10 mg nickel sulfate hexahydrate/kg-day or equivalent to 2.2 mg nickel/kg-day) and deemed it as the LOAEL for this study.

Following the range-finding study, Springborn Laboratories (2000b) conducted a two-generation reproduction study. Nickel sulfate hexahydrate was administered at 0, 1, 2.5, 5, or 10 mg/kg-day. Dosing of the F₀ animals began at 10 weeks prior to mating and dosing of the F₁ rats began on postpartum day 22 (just after weaning, at a young age). For both generations, daily dosing of the dams was continued until lactation day 21. In this two-generation study, no adverse effects were observed even at the highest dose, 10 mg/kg-day (2.2 mg nickel/kg-day).

In reviewing these three studies in totality, OEHHA concluded that the 1.1 mg nickel/kg-day (5 mg nickel sulfate hexahydrate/kg-day) dose in the two-generation study was the appropriate NOAEL for use in calculating the PHG. It represents the highest NOAEL that is lower than the LOAEL from either the Smith, or Springborn range-finding, study.

OEHHA applied this NOAEL in conjunction with an uncertainty factor of 1000 (10 for inter-species extrapolation, 10 to account for human variability, and 10 for database deficiencies for carcinogenic effect via oral route) for calculating a safe dose of 1.1 µg/kg-day. The safe dose was in turn used to derive the PHG.

Current Evaluation Results

Nickel has been cited in the PHG report as having adverse effects on several sensitive organ systems that are undergoing development in school children (OEHHA, 2001). For

example, it affected the hypothalamus-pituitary axis and inhibited prolactin secretion; it reduced a variety of T-lymphocytes and natural killer cell-mediated immune functions; and it impacted the reproductive system and viability of offspring. Against this background, OEHHA targeted the literature search using the criteria outlined in the Introduction Section. We came up with a list of 18 references; all of which were qualitative studies and thus not usable in the context of the current task.

OEHHA modified its strategy, which stipulated a broad-based literature search. A total of 18,410 references were compiled. These references and their abstracts were put into a Procite database. The database, in turn, was queried in an attempt to identify quantitative studies with nickel doses in the range, or below that, of 1.1 mg/kg-day. The purpose is to run another check that we have identified the "lowest" LOAEL or NOAEL during the PHG review. The results support that conclusion.

Recommendation

The current broad-based literature search has not identified data to suggest that the NOAEL should be changed from that used as the basis for the PHG. The PHG NOAEL addresses the reproductive end point that is one of the targeted organ systems for this review, and the exposure time and duration of rats stipulated in the Smith and Springborn studies covers the critical windows for exposure of pre-school and school children. As such, the PHG NOAEL should be used to develop a child-specific RD for use in school-site risk assessment.

OEHHA has considered the appropriateness of using an oral absorption factor for calculating the chRD for nickel. OEHHA noted that human absorption of nickel depends on the dietary matrix (OEHHA 2001). Absorption is significantly higher when water is used as the administration vehicle, compared to when food is used. Alexander et al. (1974) estimated a 40 percent absorption for healthy children on a balanced diet that consisted of milk, cereal, and other food. McNeely et al. (1972), on the other hand, estimated a 1.6 percent absorption for adults on a regular diet (water and food). These data suggest the appropriateness of applying a child protective factor of three to account for the absorption difference between children and adults.

Because a PHG can be based on a cancer or non-cancer endpoint, OEHHA applied a factor of 10 to account for database deficiencies for carcinogenic effect via oral route in deriving a PHG safe dose for nickel. Since a non-cancer chRD by definition addresses the non-cancer endpoint only, OEHHA in this situation has not applied that database deficiency factor in calculating the chRD for nickel.

Calculation of the chRD for nickel is based on the following equation:

$$\text{chRD} = \frac{\text{NOAEL}}{\text{UF} \times \text{CP}} = \frac{1.1 \text{ mg/kg-day}}{100 \times 3} = 3.7 \text{ } \mu\text{g/kg-day}$$

Where,

- NOAEL = No-observed-adverse-effect-level from Smith et al., 1993; Springborn Laboratories, 2000a, b.
- UF = Uncertainty factor of 100 (10 for inter-species extrapolation, 10 for human variability).
- CP = Child protective factor of 3 to account for the GI absorption difference between children and adults.

Accordingly, OEHHA is proposing a non-cancer chRD of 3.7 $\mu\text{g}/\text{kg}\text{-day}$ for nickel to be used in school-site risk assessment.

3. Conclusion

This report summarizes OEHHA's evaluation of cadmium, chlordane, heptachlor (and its metabolite heptachlor epoxide), methoxychlor, and nickel. Based on the evaluation, OEHHA proposes to establish a chRD for each of these chemicals pursuant to the second part of Health and Safety Code Section 901(g). They are listed in Table 3.1 along with other pertinent numerical health criteria.

Table 3.1 Numerical Non-cancer Health Criteria

	OEHHA's Proposed chRD (mg/kg-day)	OEHHA's PHG Safe Dose (mg/kg-day)	U.S. EPA's RfD (mg/kg-day)
Cadmium	1×10^{-5}	1×10^{-5}	5×10^{-4}
Chlordane	3.3×10^{-5}	1×10^{-5}	5×10^{-4}
Heptachlor	3×10^{-5}	1×10^{-4}	5×10^{-4}
Heptachlor epoxide	1.3×10^{-5}	1.3×10^{-5}	1.3×10^{-5}
Methoxychlor	2×10^{-5}	5×10^{-3}	5×10^{-3}
Nickel	3.7×10^{-3}	1.1×10^{-3}	2×10^{-2}

Dear Mr. Ritchie:

**COUNTY OF LOS ANGELES BOARD OF SUPERVISORS
FINAL COMMENTS ON LAX MASTER PLAN DRAFT SUPPLEMENTAL EIS/EIR**

On behalf of the Los Angeles County Board of Supervisors, I am submitting final comments on the Supplement to the Draft Environmental Impact Statement/Environmental Impact Report (Supplemental Draft EIS/EIR) for the Los Angeles International Airport Master Plan. The Board of Supervisors approved these comments for submission at their meeting of October 28, 2003.

The Board of Supervisors looks forward to receiving a written response to the comments.

Sincerely,

DAVID E. JANSSEN
Chief Administrative Officer

1.0 BACKGROUND AND EXECUTIVE SUMMARY

1.1 BACKGROUND

During 2001, A.C. Lazzaretto & Associates was retained by the Los Angeles County Chief Administrative Office to review and comment on the Draft Environmental Impact Statement/Environmental Impact Report (DEIS/EIR) prepared for Los Angeles World Airport's (LAWA) Proposed Los Angeles International Airport (LAX) Master Plan. The 2001 Draft EIS/EIR addressed three build alternatives, a no-build alternative, and the existing setting for the Los Angeles International Airport (LAX) Master Plan.

A.C. Lazzaretto & Associates assembled a team of environmental review experts to review the document for consistency and accuracy. Working in collaboration with County staff, a detailed comment letter was prepared and submitted to LAWA on 28 June 2001. Thereafter, in response to considerable public comment and the terrorist attacks that occurred on September 11, 2001, LAWA suspended work on the earlier EIS/EIR to develop a fourth alternative -- Alternative D, the Enhanced Safety and Security Plan. LAWA made a Supplement to the Draft EIS/EIR (SDEIS/EIR) available for public comment in July of 2003 to update information presented in the Draft EIS/EIR and to integrate Alternative D into the environmental review process. The Supplement offered no response to comments submitted on the 2001 DEIS/EIR.

Alternative D includes a number of airfield facility modifications. Although LAX would continue to operate with 4 runways, 2 of the existing runways would be moved, two would be lengthened, and all would be further separated from one another. New centralized passenger terminals would replace the existing parking structures. The existing Terminals 1 through 7 would be reconfigured, including a new north/south linear concourse at the Tom Bradley International Terminal, flanked on the west by a new satellite concourse. A new ground transportation center and intermodal transportation center to be built east of Aviation Blvd. would serve as the primary access for all passenger drop-off and pick-up and vehicle parking. Some cargo facilities would be modified, although overall square footage would be equivalent to the No Action/No Project Alternative.

Following publication of the SDEIS/EIR, the Los Angeles County Chief Administrative Office again retained A.C. Lazzaretto & Associates to review and comment on the revised document. A.C. Lazzaretto & Associates in turn assembled the team of environmental review experts that had reviewed the 2001 document, in order to assess the 2003 Supplement for consistency, accuracy, and changes since the original Draft EIS/EIR was prepared. The information has been evaluated using the following criteria: reasonableness of input data and assumptions, appropriateness and accuracy of analyses and mitigation measures, and conformity with requirements of the California Environmental Quality Act (CEQA) and the National Environmental Policy Act (NEPA).

Results of the current review indicate that many of the concerns expressed in our earlier comment letter still remain, including one that was central to County comments on the earlier LAX Master Plan review: although LAWA indicates that its goal is to limit growth, improvements proposed as part of Alternative D would in reality serve to reinforce LAX as the preeminent airport of the southern California region, and may undermine attempts to strengthen the role of outlying airports. There are a number of points, in addition to this thematic concern, that merit further consideration and discussion before LAWA considers certification of the Supplement to the EIS/EIR and approval of the preferred alternative.

To facilitate LAWA's review and response, the County has revised and updated the comment letter originally submitted in June of 2001. The current comment letter incorporates all issues for which a response is sought from LAWA. As before, the review team has paid special attention to the major issues of noise, traffic, environmental justice, and air quality, and the team has again made every attempt to offer objective, constructive comments concerning the major elements of the Supplement to the DEIS/EIR.

1.2 EXECUTIVE SUMMARY

A.C. Lazzaretto & Associates has been retained by the Los Angeles County Chief Administrative Office to review and update comments on the 2001 Draft DEIS/EIR prepared for LAWA's Proposed LAX Master Plan, consistent with changes in the current 2003 Supplement to the Draft EIS/EIR. The 2001 Draft EIS/EIR addressed three build alternatives, a no-build alternative, and the existing setting for the Los Angeles International Airport (LAX) Master Plan. The 2003 Supplement incorporates a new Alternative D (the "enhanced safety and security plan") that LAWA has designated as the preferred project option. To address safety issues, the review team has been expanded to include participation by BoydForbes, Inc., a renowned airport safety consulting firm based in Denver.

The County has a special responsibility in this process, since it represents the unincorporated communities that are most directly impacted by LAX operations. It is for this reason that the County has taken a highly active stance during 2001 and 2003, and in both instances we have focused on issues of greatest concern to our constituents. During 2001, we submitted comments to LAWA in which we expressed a number of serious concerns. With publication of the 2003 Supplement we find that most of our earlier concerns remain unaddressed and new issues have been identified that are of even greater potential concern for Los Angeles County constituents. The County has twice sought to meet with LAWA's consulting team to discuss these issues, and on both occasions has been rebuffed. In so doing, LAWA has bypassed an opportunity for identification of joint solutions that could facilitate improvements at LAX while minimizing impacts on LAX's neighbors living in Manchester Square, Lennox, Westchester and other adjoining communities. Manchester Square is that area bounded by La Cienega Blvd. on the east, Century Blvd. on the south, Aviation Blvd. on the west, and Arbor Vitae Street on the north.

Fundamentally, the County of Los Angeles believes that LAWA is proposing to implement a flawed project, and that LAWA has developed an inadequate environmental document to review the project. The following report covers a wide range of issues, many in considerable detail. While all of these issues are important, we would like to call special attention to the following key points:

- ▶ Contrary to statements made throughout the SDEIS/EIR, our review clearly shows that Alternative D will not constrain growth at LAX. LAWA has misrepresented this alternative, to the jeopardy of the environmental analysis.
- ▶ Alternative D will also not serve the security goals for which it was formulated. The Plan focuses on hardening security for the east-side entry to LAX but largely ignores the perimeter, maintenance/fuel farm, and cargo areas -- leaving the back door wide open.
- ▶ The separation concept is diminished in value by the expensive and vulnerable mass transit link proposed between the Central Terminal Area and remote landside ground facilities. It is further diminished by the lack of Flow Process Mapping data; the consequential risk of task

overload and failure to achieve target reduction; and by the potential alienation of a public that may perceive screening requirements as excessive.

- ▶ The Security plan relies heavily on technologies, some of which have been discredited (e.g., facial recognition surveillance). Additionally, greater thought must be given to the risk of data saturation. Over-dependence on security technology may lead to higher risk of error and, ironically, diminished protection.
- ▶ There are a number of existing, unexplained security exposures at LAX, including several areas characterized by extreme weakness in access control, that should be remedied as soon as possible; it is recommended that LAWA take steps to close Pershing Drive to public traffic as soon as practicable.
- ▶ Use of a Supplement to the 2001 Draft EIS/EIR was improper under guidelines for CEQA. LAWA should have addressed Alternative D in a comprehensive revised draft EIS/EIR in which the full record of information was available for public review and agency decision-making.
- ▶ The Purpose & Need statement emphasizes LAX's role in meeting regional growth, investment return, and international trade, and claims that Alternative D will fill these objectives. Yet the EIS/EIR asserts that Alternative D has the same socioeconomic characteristics as No Action, but for construction jobs, and finds that No Action would fail to meet project purpose and need. Either Alternative D fails to meet the stated goals, or Alternative D has not been described in accordance with full disclosure requirements.
- ▶ The environmental assessment does not offer a reasonable range of Alternatives that would feasibly meet most objectives, but would avoid or lessen significant effects of the project, and thus the SDEIS/EIR fails to fulfill the "Rule of Reason."
- ▶ Scoping Outreach did not include input from Los Angeles County Government or the public at large regarding either Alternative C (the 2001 preferred project) or Alternative D (the 2003 preferred project) and thus fails to meet basic NEPA requirements.
- ▶ The SDEIS/EIR offers a baseline now 7 years old: conditions in 1996 do not represent the baseline of 2003. The events of 9/11 changed the baseline so fundamentally that LAWA withdrew its 2001 documents to formulate an entirely new preferred project. The 1996 baseline does not offer a reasonable yardstick against which to measure the impacts of Alternative D or any other project alternative (including No Action).
- ▶ Piecemeal efforts to remedy the outdated baseline have further obscured understanding. The frequent shifting from one baseline nomenclature and timeframe to another is, at best, confusing. At worst, it conceals the underlying impacts that this 2003 Supplemental Draft EIS/EIR is intended to illuminate.
- ▶ The most pressing problems at LAX are lack of adequate runway length on the north complex, the security threat of private autos near the terminals, and lack of international gates. Yet the Phase One construction plan addresses none of these for many years and instead concentrates on the airport fringes (the GTC and ITC) and on demolishing and rebuilding perfectly useable terminals to accommodate New Large Aircraft. This sequence does not match the environmental and congestion priorities evident at LAX.
- ▶ The SDEIS/EIR contains numerous comments and statements that create an appearance of project advocacy. Even the appearance of advocacy is inappropriate given the policy guidelines contained in CEQA and NEPA and it seriously undermines confidence in the objectivity of the Draft EIS/EIR and its commitment to full disclosure.
- ▶ The 2001 DEIS/EIR was found to lack even the most elementary NEPA requirements for Environmental Justice; many deficiencies remain in the 2003 SDEIS/EIR. In particular, Alternative D shifts many impacts toward the more economically disadvantaged

communities east and northeast of LAX, and appears to protect biological resources at the expense of residents in Lennox, Inglewood & Manchester Square.

- ▶ The document fails to disclose issues and concerns raised in Environmental Justice (EJ) workshops, defers evaluation of critical environmental justice impacts (including Air Quality and Health Effects) due to lack of data, offers ill-defined mitigations, and offers a preferred project that protects butterflies at the expense of residents and schoolchildren.
- ▶ The noise assessment contains significant discrepancies in the number of dwelling units and population impacted between the baseline year and the data published by LAWA. Additionally, there is an unexplained discrepancy in the year 2000 noise contours shown in the 2001 and the 2003 documents.
- ▶ The 2001 EIS/EIR acknowledged that it omitted quantitative assessment of toxic air pollutant exposure due to lack of time; the 2003 document also omitted this assessment, but did not so note. Completion of such studies independent of the environmental review, as proposed, would preclude establishment of baseline conditions. LAWA decision-makers will be unable to make an informed project determination until this data is developed and disclosed. The noise modeling results were based on inadequate flight track data.
- ▶ Nitrogen oxides were determined to have significant impacts before and after mitigation, but would be reduced the least under the proposed mitigation measures. The proposed mitigation measures do not appear to successfully address nitrogen oxides.
- ▶ The 'ratioing' technique used to update the analyses of airport pollutant sources for Alternatives A, B and C, and No Action, makes it difficult to fairly compare the alternatives.
- ▶ LAWA Decision-Makers will not be adequately informed until the environmental documentation provides thorough review of the following alternatives:
 - ▣ Relocation of New Large Aircraft Facilities to Another Airport
 - ▣ Major Shift of Airport Facility Improvements from East (Human Habitat) to West (Butterfly Habitat)
 - ▣ Development of a Minimum Airport Improvement Plan incorporating only High Priority elements

The County looks forward to reviewing LAWA's responses, particularly with respect to the additional commitments requested throughout this comment letter. At the same time, the County believes that LAWA's interests would be best served through preparation of a *comprehensive revised Draft EIS/EIR* in which *the full record* of information is consolidated in a manner that facilitates public review and agency decision-making.

2.0 INTRODUCTION TO THE COMMENT LETTER AND REPORT ORGANIZATION

A.C. Lazzaretto & Associates has again been retained by the Los Angeles County Chief Administrative Office to review and comment on a Supplement to the Draft Environmental Impact Statement/Environmental Impact Report (SDEIS/EIR) prepared by Los Angeles World Airport (LAWA) to address the impacts of a proposed Master Plan for Los Angeles International Airport (LAX). The SDEIS/EIS was issued in response to considerable public comment on the Draft EIS/EIR and Master Plan presented during 2001 and in response to the terrorist attacks that occurred on September 11th of that year. The SDEIS/EIR introduces a new preferred alternative -- Alternative D, the Enhanced Safety and Security Plan. In reviewing the Supplement, we have again noted the high quality of writing, and the thoughtful organization and presentation of materials that is evident in many of the technical reports. We again conclude, however, that the documents are substantially compromised by significant errors, omissions, and biases. We submit

that LAWA has used improper procedures -- under CEQA and NEPA -- to introduce the new preferred Alternative D, and we conclude that LAWA has offered misleading statements concerning the potential for further growth at LAX.

The review team assembled by A.C. Lazzaretto & Associates includes all firms who contributed to the 2001 review, as well as a new firm – BoydForbes, Inc. – that was brought in to review the highly technical, and critically important issues pertaining to airport safety and security. Based in Colorado, BoydForbes, Inc. is one of a handful of firms that specialize in airport security and have the ability to critically review the environmental documentation pertaining to this topical issue. Team members who also participated in the earlier effort include Michael Brandman Associates, Bauer Environmental Services, Austin-Foust Associates, and Mestre Greve Associates. Each of these firms is a leader in the field of environmental review and key members have extensive experience working with the environmental review of airport projects.

In performing the task of reviewing the Draft EIS/EIR, the County has made every attempt to offer objective, constructive comments concerning the major elements of the Draft EIS/EIR. We have made note as appropriate where issues may involve diverse views among experts.

The following report is organized to facilitate LAWA's review and response to the issues raised. As such, the general flow of this review document follows the topic pattern of the Supplement to the DEIS/EIR; however, there are many sections that have been rearranged in order to emphasize a particular point or to clarify the issue at hand. This is particularly true in the following discussion (§3.0 below) which deals with general issues that are evident throughout the SDEIS/EIR document and are not specific to any single section.

This document focuses only on issues of concern to the County from a legal standpoint, and does not attempt to identify or discuss those sections in the SDEIS/EIR that appear to meet State or Federal guidelines. This is not to say that sections not mentioned in this document can be assumed adequate; rather, the sections are omitted from this document in order to focus on areas of greatest concern to the Los Angeles County Board of Supervisors.

3.0 GENERAL ISSUES

This section identifies issues that are evident throughout the entire Supplement to the DEIS/EIR document. Typically, the issues raised in this section deal with the backbone of the SDEIS/EIR and, therefore, the errors, omissions, and faulty conclusions identified herein are those that compromise the validity of the Supplement to the Draft EIS/EIR as a whole.

3.1 ALTERNATIVE "D" DOES NOT CONSTRAIN GROWTH AT LAX

3.1.1 Airside Gate Frontage Far Exceeds Stated Levels

The SDEIS/EIR claims that Alternative D would serve, in the year 2015, no more passengers than would be expected with current airport facilities (approximately 78 Million Annual Passengers [MAP]). Despite massive improvements to the capacity of the runways and terminals, the SDEIS/EIR also claims that passenger limits will be assured by limiting "airside gate frontage." These assertions do not hold up to scrutiny. In fact, Alternative D increases "airside gate frontage".

increases the number of aircraft gates, and increases aircraft gate efficiency beyond the levels contained in the No Project Alternative. The Master Plan states that:

“Alternative D is described as constrained because...facilities would not be designed to accommodate the unconstrained aviation demand forecast profile. Specifically, the terminal frontage available in Alternative D to park aircraft side-by-side is less than the equivalent terminal frontage available in the No Action/No Project Alternative.” (emphasis added)

Further, the Supplement to the EIS/EIR states:

“The net effect of these terminal changes would be a reduction in the total airside gate frontage available for aircraft gates and in the number of available aircraft gates to match the peak gate requirements identified in the Alternative D design day schedule.”

Neither the Supplement to the Master Plan nor the Supplement to the Draft EIS/EIR provides any further explanation, data or calculations to substantiate those statements. On the contrary, as shown on the attached table, Aircraft Gate Comparison, various graphics in the Master Plan provide evidence directly contravening those statements.

**Table 1
AIRCRAFT GATE COMPARISON
EXISTING, NO PROJECT & ALTERNATIVE ‘D’¹**

Terminal	1996 Existing			2015 No Project		Alternative D		
	Air Carrier Contact Gates	Commuter Parking	Frontage Length (ft.)	Air Carrier Contact Gates	Commuter Parking	Air Carrier Contact Gates	Commuter Parking	Frontage Length (ft.)
1	14	6	1,740	16	0	0	0	0
2	10	0	1,201	10	0	0	0	0
3	12	3	2,104	12	0	0	0	0
4	10	10	n/a	13	0	16	0	n/a
5	16	0	n/a	16	0	16	0	n/a
6	10	14	n/a	13	0	13	0	n/a
7	12	0	n/a	12	0	15	0	n/a
8	8	0	n/a	8	0	0	19	n/a
TBIT	12	0	2,111	12	0	19	0	3,184
Remote	0	0	0	19	33	0	0	0
New West	0	0	0	0	0	27	13	4,148
New North	0	0	0	0	0	15	0	3,416
TOTAL	104	33	7,156	131	33	121	32	10,748

The amount of “airside gate frontage available for aircraft gates” is easily calculated using scaled drawings contained in the Master Plan. As shown on the attached Table 1, Alternative D includes an increase of nearly 3,600 linear feet of terminal frontage: Terminals 1, 2 and 3 will be replaced by the New North Terminal; Tom Bradley International Terminal will be reconfigured; and a New West Terminal will be built. No changes will be made to Terminals 4 thru 8. The total *existing*

¹‘1996 Existing’ data obtained from Master Plan Figure II-3.2; ‘2015 No Project’ data obtained from Figure ES-1; ‘Alternative D’ data obtained from Figure 2.2-4.

frontage of the terminals being modified is thus 7,156 feet; following proposed modifications, the terminals will encompass 10,748 feet — an increase of 3,592 feet. To substantiate its claim concerning existing conditions, the Master Plan must be including the “remote gates” that are little more than apron area where aircraft are parked. These areas with their low efficiency are not a suitable comparison to actual aircraft gates with jetways linked to a terminal. To suggest differently is to ignore well-established planning factors for passenger processing.

The number of aircraft gates also increases with Alternative D. The Master Plan Supplement uses figures in its summary tables to indicate that the No Project Alternative has 163 gates and that Alternative D has 153 gates -- indicating a reduction. However, these figures do not correspond to other figures in the Master Plan. For example, Table ES-2 in the Master Plan Supplement indicates 115 contact gates² and 48 remote gates for an existing total of 163. However, Figure II-3.2 of the Existing Conditions Working Paper (Chapter 2 of the Draft Master Plan), provides a detailed accounting of all existing gates and aircraft parking spaces, and it shows quite clearly that there are only 104 contact air carrier gates at present. Additionally, it shows 33 parking places for commuter aircraft located adjacent to terminals 1, 3, 4 and 6 and accessed via stairways. Except for one passing reference to 36 Narrow Body Equivalent Gates with access to the Bradley Terminal, Chapter Two makes no mention of the 19 remote gates in the northwest corner.

In the No Project Alternative, some of the parking spaces used for commuter flights have been converted to parking spaces for air carriers, and those spaces are now counted among the air carrier gates in the No Project Alternative. Furthermore, the 19 remote aircraft parking spaces have become prominent in the SDEIS/EIR No Project Alternative, implying that there are now 131 “gates” for air carriers and 32 “gates” for commuters. In reality, there are no more true contact gates today than there were in 1997. It is only that some existing concrete apron space formerly used for maintenance and other uses is now being used on a regular basis to park scheduled aircraft. This practice requires that passengers are bussed to the terminals, in a manner that the Master Plan admits is costly and inefficient. In simpler terms, there are now 112 air carrier parking spaces adjacent to the terminals, 19 remote air carrier parking spaces in the northwest corner, and areas for parking approximately 32 commuter aircraft at two remote locations.

Aircraft gates for Alternative D are depicted very clearly on Figure 2.2-4 Gate Layout and Utilization in the Supplement to the Master Plan. This Figure shows 121 air carrier contact gates and 32 parking spaces for commuter aircraft and/or regional jets. Alternative D also includes the conversion of 8 existing air carrier contact gates in Terminal 8 to spaces to park 19 commuter turbo props/regional jets.

The evidence is quite clear that Alternative D provides 8 more air carrier contact gates than the No Project Alternative, and in a configuration that is more efficient.³ Additionally, under Alternative D LAWA retains the flexibility to create remote gates on available apron space. As the historical evidence shows, LAWA has not prepared environmental documentation for similar operational modifications at LAX in past years. Furthermore, LAWA could easily retain the eight contact gates in Terminal 8, thereby boosting the total for Alternative D to 129 contact gates – 15% more than the existing LAX layout. Accordingly, under Alternative D LAWA has the potential to

² A “contact gate” includes traditional numbered gates in the terminal and a jet way to a waiting aircraft.

³ Linear configurations offer more flexibility than the current cul-de-sac design; the Construction Phasing Plan notes that the reconstruction of terminals 1, 2, & 3 into a linear configuration will create a “continuous Group VI flightline.”

increase the number aircraft gates, increase airside terminal front footage, replace inefficient aircraft gates with more efficient ones and create additional remote gates.

3.1.2 Runway Design Capacity is Understated

The preferred alternative will also serve future growth through the proposed runway design: the runway configuration for Alternative D has the same or higher capacity as Alternative C -- 90 MAP. Alternative D, in the same manner as Alternative C, addresses existing runway constraints by lengthening both of the north complex runways and by increasing the separation distance between them. The fact that the new four runway system can handle more than 78 MAP is stated very clearly in the Master Plan addendum on page 3-4: *“Alternative C’s projected annual passenger activity level served is limited by the capacity of the four-runway system and is forecast to be approximately 89.6 million (air passengers.)”* Given that Alternative D uses the same 4-runway configuration as Alternative C, and Alternative D extends RW 6L/24R an additional 1,000 feet farther than does Alternative C, it can be concluded that the capacity of the runways under Alternative D is the same or more than Alternative C -- approximately 90 MAP.

3.1.3 Passenger Levels will be Much Higher than Forecast for Alternative D

Alternative D will allow unconstrained growth through the year 2015. Unlike the most recent FAA forecasts, the “unconstrained forecast” of 98 MAP in the Master Plan has not been updated to reflect changes in the air industry that have occurred following the events of 9/11. The most recent FAA Terminal Area Forecasts for LAX indicate that service levels at LAX will not reach the year 2000 levels (64 MAP) until the year 2008 and that service levels in 2015 will be approximately 81.6 MAP. Using those figures, Alternative D provides little if any constraint on growth.

Alternative D understates the passengers per operation. Alternative D accommodates the new Super Jumbo A380 (referred to in the Master Plan as the New Large Aircraft by creating a separation of 1040 feet between the two northern runways and by demolishing terminals 1, 2 and 3 and reconstructing a “continuous Group VI flightline.”⁴ The arrival of the New Large Aircraft, with almost 600 seats, will increase the passenger handling capacity of the runways and airspace by increasing the number of passengers per aircraft operation. Nevertheless, the Master Plan forecasts that Alternative D will have a lower number of passengers per operation than Alternative C and in fact forecasts a lower number than currently exists. As indicated on Table 3.3-1 of the Master Plan Addendum, Alternative D is forecast to have only 121.06 passengers per air carrier operation, while Alternative C is forecast to have 124.95. The table fails to include the actual numbers for the years 1996 and 2000. However, information from the LAWA web site indicates that passengers per air carrier operation totaled 109.5 in 1996, 119.65 in 2000, 116.62 in 2001, 123.18 in 2002, and 125.4 thru July of 2003. The number of passengers per operation is expected to continue to increase as airlines increase the size of aircraft and increase their load factors (percentage of sold seats.) Furthermore, there is a large and unexplained increase in the number of commuter flights (from 109,000 in Alternative C to 183,000 in Alternative D). Commuter flights average only about 20 passengers per aircraft. If some of the capacity used for commuter operations was used instead for air carrier operations, the number of passengers would again increase. There is thus abundant evidence that the runway capacity proposed under Alternative D is much greater than 78 MAP.

⁴ In contrast, the south runways will be separated only by 795 feet which is sufficient for aircraft such as the B747.

3.1.4 Terminal Space in Alternative D is Equivalent to Alternative C

Alternative D increases terminal space by 70%. The proposed increase in terminal space from 4 million square feet (msf) to 6.8 msf represents a considerable increase -- 70% higher than existing. The resulting capacity is only 8% less than Alternative C, again indicating an ability to handle many more than 78 MAP.

3.1.5 The No Project Alternative Cannot be used to Evaluate Alternative D.

Comparison with the No Project Alternative does not provide a reasonable basis to conclude there will be no additional growth. As discussed below in §3.4.2, the origins of the service levels used in the No Project Alternative are obscure and undocumented, thus casting some doubt upon their validity. If the No Project service levels are inflated, as we anticipate, then Alternative D would surely be promoting growth as the service levels increased from the current 55 MAP to 78 MAP.

3.2 IMPROPER USE OF A SUPPLEMENT TO THE DRAFT EIS/EIR

The CEQA Guidelines state that a Supplement to an EIR may be prepared if changes to a project are not considered major (§15162(a)). Where the changes necessitate major revision to a previous EIR, CEQA requires preparation of a Subsequent EIR. Both types of documents must receive the same notice and public review requirements as the original EIR. However, in a Subsequent EIR, *all information* must be presented, whereas in a Supplemental EIR only *new or revised information* need be presented. Discussion provided in Public Resources Code §21166 (and CEQA Guidelines §15162 and §15163) indicate that both types of review are intended for use in connection with *previously certified or approved* environmental documents. For documents that have not yet been certified, CEQA outlines a procedure for recirculation. Discussion provided with the CEQA Guidelines states specifically that, "*Circulating a subsequent EIR or supplement to an EIR is not "recirculation" as described under §15088.5.*"

In the present case, there is no previously certified or approved document. Furthermore, review of the Supplement to the Draft EIS/EIR provides incontrovertible evidence that changes to the proposed project are major and affect the entire environmental assessment: LAWA has presented an *entirely new alternative* as the preferred project, and the alternative was *created to meet safety and security challenges that did not exist in 2001*. In effect, the entire framework for this project -- from the baseline conditions, to the project purpose and need, to the very project itself -- changed following September of 2001, and yet LAWA used a CEQA format intended for minor changes to a certified EIR.

Finally, the format used by LAWA serves to obfuscate rather than facilitate understanding of this complex project.⁵ Every reasonable interpretation of CEQA would indicate that LAWA should have addressed the project through preparation of a comprehensive revised Draft EIS/EIR, in which

⁵ At a minimum, the SDEIS/EIR Index (§7.7) could have provided the reader with a more listing of topical issues and where they can be found, along with a cross reference to text discussions in the 2001 and 2001 documents. Instead, the Index offers only a cursory guide to topical discussions (for example, the Index contains no references for "cumulative impacts") and provides no useful tools for locating or accessing analyses from the 2001 Draft EIS/EIR.

the *full record* of information was consolidated in an effort to facilitate public review and agency decision-making.

Public review and lead agency decision-making would also have been far better served by providing copies of the comment letters submitted during public review of the original EIS/EIR. During 2001, the County of Los Angeles devoted considerable time, public funds and staff effort to review and submit comments on the extensive Draft EIS/EIR and Master Plan documentation released by LAWA at that time. Surely a similar effort was spent by many other agencies, organizations and individuals, and it is probable that the collective comments contained a wide range of information that would have been relevant to the current review. Despite this fact, the Supplement to the Draft EIS/EIR makes no effort to present *or even summarize* the earlier comment letters. This approach creates a process that is confusing and cumbersome for reviewing agencies and organizations, and thwarts an opportunity to advance public participation. A response to the earlier comments would have served to advance public discourse, strengthen the opportunity for environmental protection, and facilitate an understanding of the Lead Agency's thinking on a wide range of key issues. We acknowledge that LAWA was under no obligation to respond or acknowledge the earlier comment letters. However, the failure to have done so belies a continuing pattern of disinterest in public views that was established in 2001.

3.3 INCONSISTENT PURPOSE & NEED STATEMENT

The apparent contradiction between SDEIS/EIR statements and actual intent is also evident in the discussion of project purpose and need. The SDEIS/EIR states, on page ES-1, that the purpose and need for the project have not changed:

"The purpose and need for the LAX Master Plan has not changed since the publication of the Draft EIS/EIR...In particular, the Master Plan project objectives are to:

- ▶ *Respond to local and regional demand for air transportation during the period 2000-2015, taking into consideration the amount, type, location, and timing of such demand.*
- ▶ *Ensure that new investments in airport capacity are efficient and cost-effective, maximizing the return on existing infrastructure capital.*
- ▶ *Sustain and advance the international trade component of the regional economy and the international commercial gateway role of the City of Los Angeles."*

In a number of text discussions, the SDEIS/EIR affirms that Alternative D responds to the stated purpose and need for this Master Plan, as shown in the excerpts below from pages 2-1 and 3-25:

"Alternative D, the "Enhanced Safety and Security" alternative, offers a well-planned and rational 'regional approach' alternative for improvement of LAX. Alternative D would respond to future demand for air transportation by encouraging, but not requiring, other airports in the Los Angeles area to increase capacity to make up for the limitations of LAX. It would allow airlines to accommodate the demand for international aviation at LAX to the greatest extent possible without otherwise increasing capacity of the airport generally. It would also maintain the return on existing capital investments at LAX. Thus, Alternative D would allow the Los Angeles region to realize some of the important economic benefits outlined in the Draft EIS/EIR, while at the same time enhancing security and safety at the airport and significantly reducing environmental impacts from airport operations to the surrounding communities."

“Alternative D, as stated previously in § 3.1, Formulation and Refinement of Alternatives, of this document, is a direct response to the strongly expressed desire of many citizens, as indicated in comments received on the Draft EIS/EIR, for a regional approach to airport planning in Southern California that is more aggressive than demonstrated by the previously considered Master Plan build alternatives. The Mayor of Los Angeles, noting the need to fully examine a regional approach to satisfy air transportation demand, directed LAWA to develop a new Master Plan alternative for the improvement of LAX. Responding to the Mayor's direction, the new alternative is designed to:

- ▶ *Enhance safety and security at LAX for users and to protect the airport infrastructure*
- ▶ *Encourage the development and use of regional airports to serve local demand by constraining the facility capacity at LAX to approximately the same aviation activity levels identified in the No Action/No Project Alternative;*
- ▶ *Maintain LAX as the International Gateway to Southern California; and*
- ▶ *Mitigate the impacts of LAX's continued operation.”*

At the same time, the SDEIS/EIR emphasizes that Alternative D is equivalent in many ways to the No Action /No Project Alternative. For example, SDEIS/EIR page ES-17 includes the following statement:

“Alternative D would encourage a long-term regional approach to serving air traffic demand in the Los Angeles basin by designing facilities at LAX to accommodate passenger and cargo activity levels equivalent to the No Action/No Project Alternative activity level, but would be designed to allow air carriers to emphasize international routes at LAX.”

The Project Description (page 3-25) expands on this theme, including the statement below:

“LAWA determined that constraining the aircraft gate frontage at the terminals is a component of the airport system that is fully within its control. LAWA can constrain the development of this frontage and believes that this will, in turn, place an effective constraint on total passenger activity at LAX. LAWA can also control the amount of available cargo warehouse and processing space at LAX. By constraining the development of these cargo facilities, total cargo activity at LAX would be constrained.”

Further, the SDEIS/EIR provides quantitative data to support these statements, as shown below with information excerpted from SDEIS/EIR Tables ES-1 and ES-2.

**Table 2
COMPARISON OF NO PROJECT WITH ALTERNATIVES ‘C’ AND ‘D’⁶**

Facility	No Action/No Project Alternative	Previously-Preferred Alternative C	Currently Preferred Alternative D
Cargo-Annual Tons	3,120,000	4,172,000	3,120,000
Total # Nominal Gates	163	168	153
Million Air Passengers	78.7	89.6	78.9

⁶ Note again that the 163 gates shown for the No Project alternative includes 52 remote parking spaces.

And yet the SDEIS/EIR claims that the No Action/No Project Alternative is seriously deficient. For example, discussion on page ES-7 states that the No Action/No Project Alternative “*would fall far short of meeting the projected demand for aviation services at LAX by accommodating approximately 78.7 million passengers (a shortfall of approximately 19.2 million) and 3.1 million tons of cargo (a shortfall of approximately 1 million tons) in 2015.*”

The SDEIS/EIR also portrays the No Action alternative as *de minimis* in the scope of its improvements, but allowing for increased passenger and cargo volumes, as shown in discussion from page 3-6:

“This [No Project] alternative includes only minor airport improvements approved as of the publication of the Draft EIS/EIR in January 2001 or that were in the planning stages at that time. The improvements include minor taxiway improvements, new cargo building space, construction of at least one off-airport parking structure, and reconstruction of an on-airport parking structure. Passenger and cargo volumes would continue to increase in response to projected demand, reaching activity levels in 2015 of approximately 78.7 MAP and 3.12 MAT, respectively.”

In essence, the Supplement to the DEIS/EIR offers the following unsupportable syllogism: Alternative D meets project goals, Alternative D is substantially the same as No Action, and No Action fails to meet project goals. As discussed more fully below (and in previous sections), we believe that this inconsistency arises from the fact that the EIS/EIR is misleading in its description of alternatives.

3.4 INADEQUATE ASSESSMENT OF ALTERNATIVES

3.4.1 Inadequate Definition and Evaluation of Project Alternatives

The SDEIS/EIR fails to comply with two cornerstone elements of CEQA – that an EIR must describe a reasonable range of Alternatives that would feasibly meet most objectives, but would avoid or lessen significant effects of the project,⁷ and that preparation of an EIR should be guided by a good faith effort at full disclosure.

The Supplement to the Draft EIS/EIR carries forward the project goals that were previously established in the 2001 DEIS/EIR. These goals included: (a) to respond to local and regional demand for air transportation during the period 2000-2015; (b) to ensure that the investment in airport capacity maximizes the return on existing infrastructure capital; and (c) to advance the role of LAX as the international commercial gateway to the region. Alternative D is presented as an option that would fulfill key aspects of the project purpose and need.

The SDEIS/EIR also emphasizes, repeatedly, that Alternative D is substantially the same as the No Action Alternative in terms of meeting transportation demand -- as measured by number of gates, number of passengers, number of aircraft operations, and cargo tonnage. Yet the No Action Alternative as presented is clearly deficient in terms of meeting demand for aviation and cargo services.

⁷ CEQA §15126.6(f) states, “Alternatives shall be limited to ones that would avoid or substantially lessen any of the significant effects of the project.”

If this inconsistency has a sound explanation, it is the job of the SDEIS/EIR to provide that explanation. Instead, the SDEIS/EIR is permeated with unexplained inconsistencies. Similar incongruities were apparent in the 2001 document. The 2001 Draft EIS/EIR presented Alternative C as the preferred action, yet concluded that Alternative C would have more significant unavoidable adverse effects than either of the other two build Alternatives (25 for C; 23 for A; 22 for B), and would fail to meet projected demand.

In this regard, both the Draft and the Supplement to the Draft EIS/EIR fall short of the requirement that environmental documents must provide a *clear definition of project goals* in association with the selected range of alternatives. As now presented, the data suggest either that Alternative D fails to meet essential aspects of the stated goals, or that Alternative D has not been described in accordance with full disclosure requirements.

3.4.2 Alternatives are Inconsistent with Baseline Data

On close review, the numbers provided in the Tables entitled “Summary of Activity, Comparison of Alternatives and Summary of Features, Comparison of Alternatives”⁸ do not present a cohesive picture. When compared with data provided throughout the baseline and impact analyses, information contained in this summary statement appears to be fundamentally lacking in logical internal consistency. For example, in describing assumptions made for the No Project Alternative, the Socioeconomic Technical Report⁹ indicates, “The schedule of operations would still show variations throughout the day but the peak period would be at or exceed the airfield’s capacity. Congestion, delays and passenger inconvenience would be common all year, not just during peak holiday periods.” However, the “Summary of Features, Comparison of Alternatives” contradicts these claims. The Summary indicates that the No Project Alternative would have: (a) fewer all-weather delays than Alternative C (13.2 vs.13.6); (b) fewer annual cancellations than Alternatives A and C (9,969 vs. 15,477 and 15,814); (c) more public parking stalls than Alternative B; and (d) the same number of all-weather peak operations and 3-hour average operations.

Similar inconsistencies occur with the addition of Alternative D. Most notably, the Design Day activity levels should approximate those for Alternative C given that the runway improvements are nearly identical. Further, public parking stalls and employee parking stalls are equal to or greater than other build alternatives, and rental car acreage is doubled over other alternatives. Passenger terminal square footage is 93% of Alternative C, but the passengers are 88%. This indicates faulty project design without consistent use of planning factors.

3.4.3 Alternative D may Exceed the Stated Growth Levels

The SDEIS/EIR states that Alternative D evolved from a decision on the part of LAWA and the City of Los Angeles to limit growth. Alternative D does limit growth below that of Alternative A and B. However, as discussed in § 3.1, this alternative would not limit LAX to 78.7 MAP as claimed. Considering the extensive improvements to the airfield, passenger terminals, roadways and other facilities, it is more reasonable to assume that Alternative D will achieve service levels equaling or exceeding those of Alternative C (90 MAP). Furthermore, many elements of Alternative D resemble the Phase I construction of other alternatives: in future years, land area in

⁸ Pages ES-9 through ES-11.

⁹ Section 5.1.1.

the western part of the airport can be used for additional terminal space, and available apron space can be readily converted to remote terminal space. These possibilities merit evaluation in the SDEIS/EIR.

The SDEIS/EIR makes certain assumptions that require further explanation or verification. Why for example do commuter flights increase from 109,000 in Alternative C to 183,000 in Alternative D? If commuters fail to materialize, will the excess capacity be used for air carrier aircraft? Similarly, as discussed earlier in regard to the No Project Alternative, air cargo growth may also not be constrained.

Many of the more capital-intensive improvements in Alternative D seem to contravene the intended purposes. For example, Alternative D would require that significant resources be devoted to separating runways and demolishing existing terminals to provide for the New Large Aircraft. In fact, many major airports in the USA have already taken a position that they will not underwrite these costs. Yet easing the way for the New Large Aircraft at LAX will surely enhance the concentration of air service at LAX to the detriment of the other regional airports. If provisions for the new 600-seat New Large Aircraft were instead placed at Ontario International Airport, it would provide a powerful incentive for the airlines to increase service there. It takes many connecting flights to fill a 600 seat aircraft; if LAX is designed to accommodate these aircraft, one outcome will be to strongly reinforce the ability of LAX to attract the bulk of the region's air service.

The stated security enhancement goals can be achieved without the expense and vulnerabilities of an Automated People Mover by building the three principal ground processing landside facilities in a strategic configuration closer to the Central Terminal Area.

3.4.4 Regional Alternatives would be Best Served by Relocating New Large Aircraft Inland

The Master Plan is at odds with itself in regards to constraining or expanding LAX. As set forth in the Draft Master Plan and SDEIS/EIR, serious economic consequences will befall the region if LAX is not expanded to accommodate the unconstrained demand, and then the Supplement presents a Preferred Alternative that purports to do just that. The recent growth spurts at Long Beach and John Wayne will soon peak out. LAX will continue to attract cargo and international flights because the carriers continue to resist using other regional airports, particularly those in the inland empire. The proposed expansion of LAX and particularly the provisions for the New Large Aircraft are simply another chapter in the long history of incremental growth. As soon as these improvements are completed in twenty years or so, there is every indication that there will be another round of master planning to continue that pattern. As stated above, this master plan claims to support a regional approach to air transportation, but does not incorporate the one feature that would most secure it – i.e., relocation of the New Large Aircraft improvements to Ontario or Palmdale International Airports.

3.4.5 Additional Alternatives to Evaluate

Under CEQA, the range of alternatives addressed in an EIR should be governed by the 'Rule of Reason' which states that an EIR need only address those alternatives necessary to provide decision makers with a reasoned choice. Under this Rule, the selection of alternatives is guided by feasibility, efficacy in reducing or avoiding impacts, and ability to foster public participation and informed decision-making. 'Feasibility' includes site suitability, economic viability, availability of

infrastructure, compatibility with relevant planning documents and jurisdictional controls, and proponent access in cases where the alternative involves another location. In considering alternate locations, the “key question” to be asked is whether any of the significant project impacts could be lessened or avoided by relocating the project to another site.

Relocation of New Large Aircraft Facilities to another Airport: The Rule of Reason applies to the LAX Master Plan SDEIS/EIR, and this document will not meet the standards of adequacy until it evaluates relocation of all or part of the project to another site. The County of Los Angeles requests that LAWA provide such analysis for the following alternative: relocation of facilities oriented to the New Larger Aircraft to Ontario International and/or Palmdale International, both of which *were designed to accommodate international travel, are underutilized, and are owned and operated by LAWA.* Such an alternative would almost certainly enable LAWA to reduce project impacts around LAX substantially, without concomitant impacts at the relocation sites.

Shift Airport Improvements from the East to the West: The County also requests that LAWA evaluate an alternative in which improvements are shifted away from human habitat on the north and east and into the butterfly habitat on the west. We understand why LAWA may have wished to avoid this assessment in light of the complex background and history surrounding the El Segundo Blue Butterfly Habitat Restoration Area and the Los Angeles/El Segundo Dunes. However, the path of omission forecloses an important opportunity for informed decision-making. In this case, *the proposed Master Plan improvements will cause new, significant and unavoidable adverse new impacts to thousands of human beings* (i.e. elevated noise levels, increased single-event exposures, increased school disruption, loss of industrial jobs and historical resources, elevated pollutant levels, etc.). Due to omission *decision makers will not know* whether it may have been possible to lessen or avoid these impacts by shifting the improvements westward and instead imposing the significant unavoidable adverse impacts on a population of 7,000-87,000 endangered El Segundo Blue Butterflies. *Decision makers will not know* how the mitigation costs for the human impacts would compare with the mitigation costs for relocating butterfly habitat. Due to omission, *decision-makers will be unable fulfill their statutory obligation* to weigh, balance and consider the trade-offs, costs and opportunities associated with environmental justice and resource protection. To avoid this outcome, the County of Los Angeles asks that LAWA provide the public and LAWA decision-maker with a full and complete assessment of this alternative.

Redesign and Reprioritize Proposed Airport Improvements: Finally, in furtherance of finding an environmentally superior alternative that fulfills the basic objectives of the project, the County asks that LAWA develop, consider and comment on a new Alternative that would solve the urgent needs LAX in a timely manner and also eliminates costly, time consuming and controversial items. The following elements should be addressed:

- ▶ Fast track the addition of international gates on the west side of Tom Bradley International Terminal.
- ▶ Fast track the lengthening of RW 6R/24L in its present position.
- ▶ Widen the north complex runways by moving RW6L/24R to the north as proposed in Alternative C.
- ▶ Eliminate the Ground Transportation Center and the Automated People Mover. Prohibit private vehicles on World Way in the Central Terminal Area, and provide security screening for a fleet of zero emission vans that would serve the many airport and privately owned garages around the airport. (Note that this trend is already evident.)

- Eliminate all provisions for the New Large Aircraft including the Design Category VI spacing of the north complex runways and provision of larger aircraft gates.
- Provide additional space in the Central Terminal Area as proposed in Alternative D.
- Close Pershing Drive to all public access.

3.4.6 Scoping Outreach did not Include Alternative D

LAWA made the 2003 SDEIS/EIR available for public comment in July of 2003 to update information presented in the 2001 Draft EIS/EIR and to integrate Alternative “D” into the environmental review process. Alternative D, the “Enhanced Safety and Security Plan,” introduces numerous infrastructure and concept changes into the alternatives analysis including a reprioritization of project goals to emphasize safety. In turn, the shift in project objectives changes the manner in which alternatives must be assessed in the environmental analysis. The objectives of the CEQA process include fostering interagency coordination early in the review of projects and encourage public participation in the planning process.¹⁰ Similarly, the purpose of the scoping process required by NEPA is to identify and disclose all of the potential Alternatives under consideration by the lead agency. This provides the public with the greatest ability to understand project issues and thus contribute useful information, suggestions and comment for consideration by the lead agency decision-makers.¹¹

In the present case, the scoping outreach and early consultation with Responsible and Trustee Agencies did not include Alternative D, which became the preferred project. This denies the public of the opportunity to comment, and it also raises questions as to the validity of the process by which “D” became the preferred Alternative -- between the 1996 circulation of the Notice of Preparation (NOP), and scoping outreach, and the circulation of the 2003 SDEIS/EIR. If the objectives and scope of the project changed sufficiently between initial outreach and circulation of the Supplement to the Draft to warrant incorporation of a preferred Alternative that was not even included in the original Draft EIS/EIR, then the NEPA scoping process should have started again. CEQA also requires, at minimum, circulation of a comprehensive Subsequent Draft EIR that includes full disclosure of the alternatives analysis and process used to select the preferred Alternative.¹²

3.5 INADEQUATE AND OUTDATED BASELINE SETTING

3.5.1 The 1996 Baseline is not Applicable to Existing Conditions in 2003

The Draft and Supplement to the Draft EIS/EIR both comply with the CEQA requirement that the baseline be defined by conditions extant at the time the Notice of Preparation was released. However, because the baseline was already five years old at the time of the 2001 Draft EIS/EIR release, and is now 7 years old for analyses contained in the Supplement, the review fails to comply with the intent of CEQA to facilitate an understanding of changes in the environment associated with the proposed project. Use of the five-year old baseline, coupled with the document’s frequent assumption that mitigative actions addressing air quality, noise, traffic, water quality, and other topical issues will occur primarily (or only) through project-related activities, tends to consistently overstate the impacts of the No Project Alternative relative to other Alternatives. Although the

¹⁰ CEQA Guidelines § 15002, § 15086, and § 1587

¹¹ NEPA Guidelines: 40 C.F.R. § 1508.25

¹² CEQA Guidelines §15162(a)

2003 SDEIS/EIR provides the “normally” accepted “baseline” of conditions extant at the time the NOP was released, CEQA Guidelines by implication allow the Lead Agency to use a baseline different than the NOP released date when “non-normal” circumstances occur.¹³

In the present case, several “non-normal” circumstances have occurred that necessitate an updated baseline. In particular, the NOP is now seven years old and conditions extant in 1996 do not represent existing conditions at the project site. More significantly, the extraordinary events of September 11, 2001 significantly altered baseline conditions – physical and social – from what existed when the NOP was released. So fundamental were these changes that LAWA withdrew the then-pending Draft EIS/EIR and Master Plan, and proceeded to formulate an entirely new alternative, which it then identified as its preferred project. Clearly, the 1996 baseline material provides an inadequate yardstick against which to measure and understand the impacts of Alternative D or any other project alternative (especially including the No Action Alternative).

It is generally understood that air travel will not soon return to pre-9/11 conditions. After 9/11, LAX implemented new operational procedures that in turn changed (1) the location and distribution of passengers and visitors, (2) the length of time passengers are at the airport, (3) the number of passengers arriving, and (4) the number of aircraft taking off and landing.

For all of these reasons the 2003 Supplemental Draft EIS/EIR fails to comply with the intent and judicial interpretation of CEQA relative to the Baseline Analysis – i.e., to facilitate an understanding of changes in the environment associated with the proposed project and project Alternatives. Furthermore, use of this 7-year old baseline tends to consistently overstate the impacts of the No Project Alternative relative to other Alternatives. When coupled with the Draft EIS/EIRs frequent assumption that mitigative actions addressing air quality, noise, traffic, water quality, and other topical issues will occur primarily (or only) through project-related activities, the error is even more apparent. CEQA clearly intends that the baseline should reflect the existing level of actual development to the maximum extent possible; since the Draft EIS/EIR baseline is set at 58 MAP (vs. 67+ MAP at present – a 15%+ discrepancy), this intent is clearly unmet.

In order to achieve an adequate document, LAWA needs to provide an updated baseline for all topical sections where current data is available. Doing so will minimize the risk of an unfavorable ruling such as the situation encountered by Logan Airport in Boston. The United States Environmental Protection Agency rated the 1999 Logan Airport EIS as “Environmental Objection, Insufficient Information” for, among other concerns, the use of the outdated baseline year of 1993.

3.5.2 Baseline Terminology is Inconsistent and Confusing

The baseline data is also inconsistent. This problem extends not only to the many different years used as the “baseline”, but also to incorrect identification of the base year for given data sets. For example, the 4th quarter 1996 database cited for the noise calibration does not match actual 4th quarter data according to published noise contours.

¹³ CEQA Guidelines § 15125

**Table 3
DIFFERENCES BETWEEN EIS/EIR NOISE IMPACT
& LAWA 1996 QUARTERLY REPORT**

	Dwellings Inside 65 CNEL	Population Inside 65 CNEL
LAWA 1996 4 th Quarter Report	31,968	85,907
EIS/EIR Table 4.1-2 For 1996	16,900	49,000
Difference	15,068	36,907

The question therefore arises as to how LAWA actually defines the “Environmental Baseline.” Is the Environmental Baseline the same as the “Adjusted Environmental Baseline?” Or the “Future Without Project Scenario” (i.e., cumulative without project)? Or the “No Action/No Project Alternative?” Or none of these? Although each of these scenarios may serve a useful purpose, such gains can be realized only when the scenarios are properly defined, adequately differentiated, and consistently employed – none of which is true for the LAX Master Plan SDEIS/EIR. Does the environmental baseline include the phase-out of older, noisier Stage 2 jets, as assumed with the build Alternatives? The forecast reduction in noise exposure for Alternatives A, C and D, as compared with the No Action/No Project Alternative,¹⁴ appears to conflict with the numbers cited in the penultimate paragraph on page ES-21. It is not clear which of the congestion relief package features are scheduled for completion in Phase 1 and which will be deferred to Phase 2.

The Summary of Alternatives¹⁵ notes, in discussing baseline conditions, that “physical conditions are represented as they existed in 1997 and in more current years when possible to provide the most up-to-date information available.” It is not clear why “up-to-date” information is possible in some categories but not others. LAWA has had five years to update the information and is anticipating spending significant funds to implement the project; there is in truth no justifiable reason for denying the public and LAWA decision-makers access to current information.

LAWA must clearly define each of the baseline and future condition scenarios used in the 2003 Supplemental Draft EIS/EIR, with an explicit statement of the rationale for its use. Perhaps LAWA should delete one or more of these scenarios from discussion. Referenced scenarios include “environmental baseline,” “environmental baseline (1996),” “environmental baseline (2000),” “adjusted environmental baseline,” “environmental baseline (2015),” “non-LAX development having cumulative impact,” “future without project scenario” (i.e., cumulative without project), and “No Action/No Project”. Incredibly, the Glossary defines none of these terms. The analysis constantly shifts the baseline timeframe to manipulate the comparative assessment of project impacts -- using 1996 baseline data for traffic, air and aircraft noise, while using 2000 through 2002 for biology, earth, and water resources. The frequent shifting from one baseline nomenclature and timeframe to another is, at best, confusing. At worst, it conceals the underlying impacts that this 2003 Supplemental Draft EIS/EIR is intended to illuminate.

¹⁴ First bar chart on Page ES-22 titled, “Population Exposed to Noise Above 65 CNEL in 2015.”

¹⁵ 2001 Draft EIS/EIR, Section 3.2.1, Pages 3-8 through 3-18.

3.5.3 Baseline Terms are Not Defined

There is no clear definition of the term “Unconstrained Forecast” anywhere in the Environmental Summary or in Sections 1, 2 or 3. The reader is left to guess what the term is intended to portray, where it fits into the long-range forecasts for LAX and other regional airports¹⁶ and the estimates of rising aviation demand.¹⁷

This lack of definition and intent extends to the term “Adjusted Baseline.” This condition has never existed, and will never exist (i.e., 1996/97 airport activity and physical facilities plus 2005 and 2015 land use activity and regional traffic). There is no basis in CEQA and/or NEPA for use of this term and it therefore requires either clarification or removal from the document in favor of more traditional and more clearly defined comparative data.

3.6 PROJECT PHASING DOES NOT REFLECT STATED PRIORITIES

The proposed project phasing illustrates the Master Plan’s embrace of an environmentally inferior alternative. The most pressing problems on the airport are the lack of adequate runway length on the north complex, the security threat of private autos near the terminals, and the lack of international gates. Taxiing of loaded B747 aircraft to the south runway complex and the bussing of international passengers across the airfield creates air quality impacts, congestion, delay, and general lack of capacity. Yet the Phase I construction plan addresses none of these issues for many years and instead concentrates initially on the fringes of the airport preparing for the Ground Transportation Center and Intermodal Transportation Center, and on demolishing and rebuilding perfectly useable terminals in preparation for moving a runway to accommodate the New Large Aircraft. This sequence does not match the urgent environmental and congestion priorities evident on the airport.

3.7 APPEARANCE OF ADVOCACY

Both the Draft EIS/EIR and the Supplement to the Draft EIS/EIR contain numerous comments and conclusive statements that create an appearance of project advocacy. This is inappropriate given the policy guidelines contained in CEQA and NEPA. It undermines confidence in the objectivity of the analyses and casts doubt on the Lead Agency commitment to full disclosure. We are particularly concerned about technical assumptions that understate the growth potential and overstate the benefits of Alternative D, as paired with assumptions that overstate the adverse impacts of the No Project Alternative (please see §3.5.2 above for further elaboration of this concern).

3.8 INADEQUATE SCOPING OUTREACH

Both the 2001 Draft EIS/EIR and the 2003 Supplemental Draft EIS/EIR make frequent mention of the regional significance of LAX and of the Master Plan process. This emphasis on regional context is evident in discussions and analyses provided throughout the text, but more significantly is an integral part of the Purpose and Objectives statement. As stated, *“The purpose and objectives of the Master Plan are to provide...sufficient airport capacity for passengers and freight in the Los*

¹⁶ 2001 Draft EIS/EIR, Table 1-13.

¹⁷ 2001 Draft EIS/EIR, Depicted in the Exhibit on Page ES-3.

*Angeles region to sustain and advance the economic growth and vitality of the Los Angeles region...*¹⁸

Nevertheless, the original scoping outreach effort did not include a single agency within the county governments of San Bernardino County, Orange County, Riverside County, or Ventura County.¹⁹ Nor did the scoping outreach include any municipal agencies, airport officials, businesses, or services within any of these four counties, although many such entities would have an interest in the regional issues addressed and in the development and analysis of project Alternatives. This is a serious omission, particularly in light of the NEPA mandate to establish close nexus between project goals and project Alternatives. It may also explain why none of the project Alternatives incorporates even minimal regional elements.

Furthermore, the scoping process is intended to identify and disclose all of the potential Alternatives under consideration by the lead agency. This provides the public with the greatest ability for input and understanding into the potential project and offers an opportunity to comment. In fact, it is common for lead agencies to remove Alternatives from further consideration between the scoping process and the distribution of the Draft EIS/EIR. In this case, the scoping outreach did not include Alternative C (the 2001 preferred alternative) or Alternative D (the 2003 preferred alternative). As noted previously, this approach forecloses the opportunity for public comment and casts doubt on the adequacy of the process by which LAWA screened and selected the alternatives. In any case, the SDEIS/EIR fails to meet CEQA and NEPA standards because LAWA did not disclose the preferred Alternative D to the public prior to document release.

Furthermore, although LAWA presented the original 2001 draft master plan at a number of public meetings held specifically for minority citizens, it is unfortunate that the same level of outreach has not occurred for the Supplement to the Master Plan. The minority segment of the population will experience the greatest exposure to the effects of changes at LAX. In particular, the County's interest in this issue is again with the unincorporated Lennox community. LAWA should develop a more thorough outreach program for Alternative D that fully informs the citizens in this area of the complete range of options and how the proposed master plan would specifically affect them. LAWA should fully disclose the decision to extend runways to the east and avoid the endangered species habitat to the west along the beaches.

3.9 PROGRAM ASSESSMENT OF BASELINE, IMPACTS, MITIGATIONS

The analytic framework of the 2001 Draft EIS/EIR was described as one in which the document was meant to set the basis for "tiered" environmental review pursuant to both NEPA and CEQA.²⁰ The tiered concept assumes that subsequent environmental documents will be required to focus the analysis on site-specific, project-level issues, impacts, and mitigation measures. The 2003 Supplemental Draft EIS/EIR does describe many concepts in more detail, but continues to keep the analysis at a program level. The program-level analyses and vague mitigation commitments may not provide the Federal Aviation Administration (FAA) with an adequate basis on which to issue an "unconditional approval" of the airport layout plan (ALP). An unconditional approval assumes that

¹⁸ 2001 Draft and 2003 Supplemental Draft EIS/EIR, Section 2.1, Page 2-1.

¹⁹ Based on review of EIS Agency Scoping Coordination Letter Mailing List and other materials provided in Appx. A.

²⁰ Section 4, Pages 4-5 and 4-6.

LAWA has completed appropriate analyses for all development actions, and the circulated document does not fulfill this requirement.

3.10 GROWTH & CUMULATIVE IMPACTS MAY BE UNDERSTATED

The Supplement to the Draft EIS/EIR bases its analysis of growth inducement on projected cargo and passenger activity. It concludes that by 2015, Alternative D would yield a direct economic output of \$63.7 billion and 350,500 jobs, plus an indirect economic output of \$93.8 billion and 629,000 jobs through a multiplier effect of 1.5. The EIS/EIR assumes that all of the jobs would be within the 5-County SCAG region, 78% of the jobs would be within a 20-mile radius, and 40% within a 10-mile radius of LAX. Finally, it concludes that Alternative D would be similar in terms of job formation to the No Action/No Project Alternative, differing by an increase of about 1%. With respect to collateral development, the EIS/EIR finds Alternative D impacts equivalent to the No Project Alternative for LAX Northside²¹, Westchester Southside and Belford, and less than the No Project Alternative for Continental City and Manchester South.

In taking this approach, the document ignores the cumulative synergistic effects that would result if LAX Northside is constructed in tandem with the LAX improvements, as proposed under Alternative D (but not Alternatives A, B or C). The increase in cargo will create corresponding increases in off-airport services and place extraordinary pressures on commercial and residential land uses in the immediate neighborhood. Apart from a discussion of the proposed cap on peak hour traffic from the LAX Northside project, the Growth-Inducing Impact Analysis (which is also the Cumulative Impact Analysis for Alternative D) does not address these more localized impacts at all, even though the history of LAX shows them to be potentially significant.

4.0 COMMENTS SPECIFIC TO THE SUPPLEMENT TO THE DRAFT EIS/EIR

4.1 AIRPORT SECURITY ASSESSMENT IS INCOMPLETE

4.1.1 Summary of Findings Concerning the Analysis of LAX Master Plan Security

As detailed at length in the discussion that follows, the security content of Alternative D documentation is inconsistent and contradictory, leaving important questions unanswered and an urgent need for definitive clarification of the true policy and planning direction. The security analysis has been treated in an aloof and disconnected manner, is preoccupied with the public approaches and the eastern half of the infrastructure; and fails to address total airport security vulnerabilities and risk management planning. These inconsistencies imply an absence of coordination in the planning process. Of greater concern is the possibility that the professed emphasis on security enhancement is not the true priority in terms of planning and phased implementation.

There is a strong case for the separate ground processing facilities and for dispersal of target populations by reducing density, controlling and limiting vehicular access and proximity. Access

²¹LAX Northside is approximately 330-acres of land located on the north side of LAX (bisected by Westchester Parkway) and owned by LAWA. Tentative Map #34836, approved for this site during the mid-1980s, would allow development of about 4.5 million square feet of office, hotel, restaurant, retail, research and airport-related land uses.

roadways merit greater emphasis on security design, demonstrating a clearer commitment to specific contingencies while anticipating traffic impacts.

The separation concept is diminished in value by the expensive and vulnerable mass transit link between the Central Terminal Area and remote landside ground facilities. It is further diminished by the lack of Flow Process Mapping data, the risk of task overload and failure to achieve target reduction, and by potential alienation if the public perceives screening requirements as excessive.

For reasons discussed in this report, we believe that the Automated People Mover is a weak link in the overall security plan. Security enhancement goals can be achieved without the Automated People Mover by moving the 3 main ground processing facilities closer to the Central Terminal Area. The western half of the airport should be drawn into the Plan with all subcomponents receiving 'substantial treatment' as required of federal regulators and stated early in the analysis. In the course of addressing the western end of the airport, *and as a matter of urgency*, LAWA should conduct a detailed assessment of the vulnerability to terrorist attack. LAWA should give serious consideration to the permanent closure of Pershing Drive as a public thoroughfare.

LAWA should provide an illustration that shows anticipated concentric ring security applications along with an explanation of the capabilities for surveillance of adjoining commercial and residential neighborhoods. Finally, the analysis should offer a quantitative projection of the demands on security and law enforcement personnel, and the intended ratio of manpower to technological devices.

4.1.2 Introduction to the Analysis of the LAX Master Plan Security Component

The LAX Master Plan Security Component addresses known and implied security issues, with a focus on Alternative D (the Enhanced Safety and Security Alternative), while also referencing the more limited discussions found in the Master Plan and SDEIS/EIR documents as a whole. The events of September 11, 2001 are commonly referenced in the Alternative D documentation, and security issues predictably appear in documentation released by the City of Los Angeles on July 9, 2003. However, it has been more difficult to obtain security plan elements for earlier plan options, namely Alternatives A, B and C, and also the No Project Alternative.

Fundamental to the integrity of the exercise is simulation of the process by which an ordinary member of the public would gain access to this public documentation. Although airport security is a relevant topical in the context of environmental review, it did not receive any attention in the pre-9/11 public deliberations for the 2001 LAX Master Plan. This is an extraordinary fact considering the status of LAX as a world-class destination and departure airport. The public documentation search process is therefore discussed here because the security content, its location within the Master Plan and the priority afforded to it, bears directly on the credibility of the stated title of Alternative D, 'The Enhanced Safety and Security Initiative' and therefore upon the worth of the security planning component.

The documentation is voluminous and consequently electronic key word searches were employed to locate security related sections in the earlier documentation, i.e. up to June of 2001. Key words used included 'security', 'threat' and 'terrorism;' Master Plan documentation published during 2003 was

also searched using electronic means. The major portions of the documentation subjected to analysis from the security perspective, after search and filtering are:

- The LAX Master Plan SDEIS/EIR: Chapter 3 Alternatives (Including Proposed Action).
- LAX Master Plan Addendum Draft dated June 2003.
- Appendix I to the LAX Master Plan Addendum Draft: Comparative Security Analysis of Alternative D and the No Action/No Project.

4.1.3 Review of the LAX Master Plan Supplement to the Draft EIS/EIR

Chapter 3, Alternatives: The Introduction notes that Council on Environmental Quality (CEQ) regulations for NEPA require federal regulators to “*Devote substantial treatment to each alternative considered in detail...*” The SDEIS/EIR offers an historical explanation of the Draft Master Plan and the context in which Alternative D was developed. An excerpt from page 3-1 illustrates some of the extraordinary circumstances applicable to long-term security planning:

“Alternative D is designed to protect airport users and critical airport infrastructure in response to the increased risk of terrorism aimed at aviation and commercial assets. The Plan is designed with the flexibility to incorporate evolving federal airport security requirements. Alternative D is also designed to enhance the on-airport presence of law enforcement and emergency response teams.”

The words ‘flexibility’ and ‘evolving’ effectively equate at the time of public deliberation to ‘unknown’. The discussion of baseline conditions (Ch. 3.2) does not address security planning in terms of existing conditions, and, the discussion of airport security (Ch. 3.3.1) provides no explanation for the failure to address security planning in the pre-9/11 options. A vague attempt is made to reassure the reader that security plans are available for Alternatives A, B, and C should these be chosen (as opposed to Alternative D), yet the discussion is wholly inadequate. Noting that ‘these alternatives would provide on-airport space for the Transportation Security Administration to conduct its mission,’ the report goes on to state:

- *“At the time this supplement to the Draft EIS/EIR was published, the federal government’s security requirements were continuing to evolve and LAWA officials were working with TSA to determine and accommodate its needs to the greatest extent possible,”* and
- *“...it is anticipated that an extensive array of security features and operational practices if/as required could be accommodated by any of the build alternatives.”*

These statements suggest that the public disclosure of security plans is unnecessarily vague, and that security planning has been overly deferred to federal regulators.

The SDEIS/EIR summarizes conceptual points making up the new approach to airport security on page 3-27 under Alternative D: “*The end goal of this design concept is to achieve a new balance between the needs of both passenger security and passenger convenience.*” Besides claiming public safety and security benefits in very sweeping terms, it also refers to the physical layout of Alternative D and mentions the Master Plan boundaries. But it does not provide any detail concerning the features of the security plan that will deliver these benefits.

The description of Alternative D Facilities (p. 3-43) repeats the message that "*Alternative D is designed to be flexible in accommodating new federal security requirements.*" There follows brief mention of 'important security features' referring to elimination of private vehicles from the Central Terminal Area roadways and elimination of the public parking structures within the Central Terminal Area. This and subsequent statements are not so much 'security features' as 'security objectives' or 'security outcomes'. The difference is important, because it is the details that impart greater understanding and thereby enable the public to judge and offer comment. For example, when the text states that passengers and employees will access the Central Terminal Area via the Automated People Mover, there is no explanation of the methodologies that would be used to secure the safety of that journey. It is thus unclear that the APM would be safer than the Central Terminal Area public parking facility. The document also declares that "*The presence of law enforcement and emergency response teams would be enhanced with Alternative D.*" Although it then goes on to speak of two new Aircraft Rescue and Fire Fighting facilities, a new police headquarters and Terminal police posts, again it resorts to generalized claims of the advantages without supportive detail. In fact, the planned police headquarter (at Westchester Parkway and Emerson Avenue), is located outside of the operating boundary of the airport.

In subsequent pages (3-47 to 3-56), the following topics are listed and discussed without reference to any specific security component: Terminal Facilities; Traffic/Parking/Circulation Facilities; Automated People Mover; Cargo Facilities; Ancillary Facilities; Land Acquisition and Relocation; Collateral Development; and Proposed Phasing. The text states that publicly available data show that airport facilities have to be upgraded to improve security. However, the Transportation Security Administration is not the only arbiter of security issues. Security is becoming an integrated component across all airport functions. Given the size of the LAX Master Plan project, it is reasonable to expect discussion of the security plan for each listed action, each function and each facility. Cargo and Phasing offer good illustrations of this need: Cargo security is currently the focus of attention by TSA and others. It is unarguable that cargo security processes will affect airport operations, logistics and facilities access over the next 2 years, but the Supplement does not appear to anticipate this. Moreover, the 3-part Phasing Plan does not even acknowledge advance security preparation for a protracted construction project during which exceptional and extraordinary vulnerabilities will apply to the airport and its environs. The new police headquarter is not listed in the phasing, nor is there any apparent recognition of the significant perimeter and core security demands. All of these elements should be addressed before project commencement.

Discussion of the Preferred Alternative (Ch. 3.5) and the CEQA Environmentally Superior Alternative (Ch. 3.6) does not elaborate on the security benefits from traffic and incident management. Security plan elements discussed in other parts of the Master Plan suggest that the security surveillance and detection system will extend well beyond the airport infrastructure into the wider public environs, but there is no detail to confirm this. We request that LAWA provide further discussion, in keeping with full public accountability, so that long-term impacts can be considered.

The role of the Transportation Security Administration is briefly discussed in Chapter 4 (p. 4-698). The remainder of this subsection describes post 9/11 security measures, including government-mandated deadlines on baggage screening that LAWA states it has met, together with current and long term plans for deployment of 'inline' screening systems. A statement in this discussion indicates that: "*...TSA is in the process of developing additional recommendations and requirements to increase security at the nation's airports*" but provides no details. We request

discussion of the additional TSA recommendations and requirements and how they may be applied to the LAX Master Plan.

4.1.4 Review of the LAX Master Plan Addendum Draft June 2003

The Executive Summary to the Draft Addendum speaks of Alternative D as 'a new design approach to securing airports for the future' (page i-1). It states that "*The alternative would incorporate, to the greatest extent possible, [TSA] recommendations as they are developed as well as the latest passenger and baggage screening technologies;*" and "*...would also enhance the on-airport presence of law enforcement, surveillance, security, and response teams.*" These statements merit further explanation as to how this would be accomplished, and with what impact. The following page (i-2) describes conceptual goals for deterrence and prevention of terrorist attacks. In shorter form the goals stated are:

1. Reduced concentrations of people in the public areas of the airport;
2. Relatively rapid movement of departing passengers and baggage through the necessary processes to the secure (sterile) parts of the airport; and
3. Reducing vehicular access to the Central Terminal Area and avoiding concentrations of people and vehicles in other ground processing areas.

On the same page, it is stated that, "*Alternative D would utilize an expanded LAWA-operated FlyAway Program throughout the region to disperse passenger processing. This service would include remote check-in of passengers and baggage, and provide direct access into the Central Terminal Area. Refer to Appendix I for a detailed assessment of the security and safety features of Alternative D.*" Although the foregoing suggests that an explanation will be forthcoming from Appendix I, our analysis has shown that Appendix I *does not present a detailed assessment* as promised, especially when compared with other parts of the documentation. Accordingly, some comment is due concerning the generalizations stated in the Executive Summary.

As noted above, the third goal is to permit only known, screened and controlled vehicles into the Central Terminal Area; this means that some vehicles will still have access. Expansion of the FlyAway program throughout the region would also offer access to the Central Terminal Area. These two factors may compromise the intent to prevent vehicle bombs imposing heavy casualties in and around the Central Terminal Area. Terrorists seeking weak links in the protective systems would have the opportunity to exploit both approaches, e.g. by hijacking, stealing or attaching bombs to vehicles that they know have privileged access. The County requests further review and comment on this issue.

Furthermore, a number of questions arise about the modes of permit, identification (vehicle and driver) and screening of so-called 'controlled vehicles.' Access and special egress road design, emergency diversion contingencies, fully equipped road vehicle inspection checkpoints, chokepoints, and barriers -- all away from the concentrations of people -- come into play here. An efficient system should impose structural constraints on all roadways, with special allowance for those passengers and foreign drivers who will make mistakes or misinterpret airport road signs. This need appears to have been underestimated (in contrast, Appendix I does enter into speculative possibilities on roadway security controls) and we ask for a reassessment of this issue.

It is extremely doubtful that regional expansion of the FlyAway service can satisfactorily and consistently secure a fully screened passenger and baggage load to justify a bus being brought close to the Central Terminal Area, especially given the threat of suicide attack. The description of the proposed passenger screening systems for those passing through the Ground Transportation Center, Intermodal Transportation Center and Rental Car facilities will be discussed later, as there are some contradictions to address. But it is necessary to point out here that a 'level one' screening will not be adequate for passengers at the FlyAway bus stations. The TSA 'level two' screening would be essential, but would have to be repeated in the Central Terminal Area because of the mixing of people from different modes of access at that location. It is unlikely that LAWA can consistently operate fully equipped remote resources (and sterile station-to-bus areas) to accomplish full screening prior to embarking on the FlyAway bus, and then keep that bus closed and secure for its entire journey. Such a system is prone to error and penetration. Moreover, the 'hassle factor' from lengthy duplication of screening operations would to some extent defeat the initial reason for using this service. We request further review of the screening operations, including assessment of the feasibility of operating the remote resource to complete screening in advance of the FlyAway bus.

Still on page i-2, the document briefly describes the Ground Transportation Center as the primary pick-up and drop off for LAX passengers. It states "*The facility would combine a controlled and monitored roadway access system with first level passenger security screening and profiling to further enhance the safety and security of all passengers using LAX.*" The interested observer might wonder what this actually means. Parts of the Draft Addendum on this topic contradict other parts of the same document, creating confusion if not doubt about the ultimate intention for security risk management of the various facilities. LAWA has made an effort in the right direction, but the analysis below shows that the documentation for Alternative D must be significantly expanded before its title as the enhanced safety and security alternative can be justified.

Discussion of the Terminal/Passenger Processing Facilities for Alternative D (Ch. 2.2) includes a statement that, "*The Central Terminal Area reconfiguration would prohibit private and commercial vehicle access to the area, eliminating the threat of vehicular blast at the curb front, which exists today in the Central Terminal Area.*" What vehicles would LAWA permit to enter the area? Would FlyAway buses and 'screened, controlled vehicles' be allowed, as mentioned in the Executive Summary?

Text on page 2-20 mentions a baggage tunnel that connects the new airport terminals with the Ground Transportation Center, and notes that this tunnel would allow passengers to check their baggage at the Ground Transportation Center, with arriving passengers using the system to re-check their baggage back to the Ground Transportation Center from the Central Terminal Area. This statement is somewhat confusing -- does this refer to Skycap check-in service only? What security process would LAWA use for departing passengers? Is the baggage tunnel available for use by departing passengers who will check in at the Central Terminal Area? If so, is there a plan to screen 100% of this baggage? Further, what are the implications for synchronizing transit of passengers and their baggage to the Central Terminal Area?

Ch. 2.2.5 describes an airside secure underground Automated People Mover linking the West Satellite Concourse with the reconfigured Central Terminal Area. Given that a geological fault exists in or close to the area, we request discussion concerning the resulting safety implications as well as contingency plans for emergencies including Automated People Mover breakdown.

The Ground Transportation Center: Discussion in Ch. 2.2.8 notes the theoretical role of the Ground Transportation Center in drawing concentrations of people away from the check-in queues by separating curbside pick up, drop off, and parking. Some of the statements in this discussion require further clarification:

“...limiting large congregations of passengers by moving ticketing, security screening, and baggage claim to the Central Terminal Area would improve passenger safety and security. Passengers would be subjected to a first level security screening process at the Ground Transportation Center. It is anticipated that the process would include a random checking of baggage and passengers using sniffing dogs, video surveillance systems, and other security devices. Second level screening would occur at the Central Terminal Area; however the Ground Transportation Center would be designed to accommodate second level screening at any time.” (Underlined words relate to later comment in this review).

Eight major functions are proposed to be included in the Ground Transportation Center, including E-Kiosk check in, Skycap baggage check-in and first level ‘passenger security screening.’ We assume that the passenger screening would also apply to visitors and employees (not just passengers), but it is unclear what is meant by ‘random checking.’ The deployment of explosive detection canine units, given their limitations, suggests that far less than 100% of people and bags would be screened at the Ground Transportation Center. Please provide further clarification for this part of the plan.

Discussion of the baggage tunnel (p. 2-36) tends to reinforce the assumption that the baggage transit system between the Ground Transportation Center and the Central Terminal Area will not incorporate EDS screening or, if some check is applied, it will not be to the standard required for aircraft loading. The discussion leaves open the question as to whether passengers not using the Skycap service would be able to send baggage through the tunnel to the Central Terminal Area, but it does say ‘*Passengers that do not use Skycap baggage check-in may carry [note, not ‘must carry’] baggage on the Automated People Mover*’. There are two important qualifying statements about the process: “*Bags carried by passengers on the Automated People Mover would need to be checked by the appropriate airline in the Central Terminal Area. No airline agents are initially anticipated to be located in the Ground Transportation Area.*” The foregoing suggests a confused and difficult process, particularly for passengers who do not use the Skycap service (potentially 60% of all LAX traffic).

There is also risk of a terrorist attack via baggage used to carry a device for detonation on the APM. The terrorist objective in this case would be 3-fold: (1) killing and maiming a maximum number of Automated People Mover passengers; (2) closing a critical part of the system down; and (3) terrorizing the public so that they will not use LAX. In logistical terms an APM journey that involves loading, mixing and unloading of passenger baggage would reduce the potential frequency of Automated People Mover arrivals and departures and the subsequent loop journey time. Please comment on this issue.

Intermodal Transportation Center (ITC): The description of random screening in the ITC section (page 2-45) is almost identical to that describing the processes at the Ground Transportation Center. Also mentioned is the intent to monitor all approaching vehicles using video surveillance systems. Please see the discussion of Appendix I for further comment on this subject.

Consolidated Rental Car Facility (RAC): This section does not address security issues, and so the review process defers to Appendix I for explanation.

Ground Access and Parking: Discussion in Chapter 2.3 emphasizes means to reduce terrorist target density and the County does not dispute the validity of this approach. However, the document lacks data to show that the projected dispersal pattern would justify the expense and disruption of reconfiguration. For example, if an improvised explosive device was detonated at the Ground Transportation Center, curbside, on or near the Automated People Mover, or at the reconfigured Central Terminal Area, what casualty rate would LAWA anticipate at, say, peak travel time? Are the projected measurements of time, distance, people dispersal, response capabilities and resources proportionate to the desired gain? Part of the improved protection evidently comes from proposed blast mitigation measures that combine structural design with open space, but we request more data on the flow of people and vehicles in order to evaluate the plan. For example, if the needed dispersal percentages are achieved by adding 3 outlying facilities, is it necessary to operate an automated train system for a distance of 1.5 miles away from the Central Terminal Area? Could LAWA achieve the same goals closer in, with resultant savings and safety mitigations on Automated People Mover operations? If LAWA holds that there is a logistical and dispersal advantage by having the Automated People Mover further out, thereby staggering the flow of people, we request that an explanation of the basis for this advantage.

In discussion of the Central Terminal (Ch. 2.3.2.1) the document says that *“access points to the Central Terminal Area road system would be controlled to enhance security in the areas immediately surrounding the airport’s infrastructure.”* It then mentions FlyAway buses and vehicles cleared to drive on the secure airside. This appears to open a security loophole. Would it not be better to provide FlyAway passengers with a dedicated lane or fast track, using the public entrance to the Central Terminal Area while having their baggage processed through the level two TSA screening checkpoint? It appears feasible to screen all FlyAway buses, passengers and baggage with a unit contracted or employed by LAWA with TSA approval. Sufficient user numbers within the FlyAway expansion plan would justify this investment. Moreover, this additional service feature, once given the security planning attention it requires, may offer a more cost effective use of reconfiguration, in addition to its target dispersal contribution. Please comment on this proposal.

Discussion of the Ground Transportation Center (p. 2-60) mentions use of video surveillance to monitor activity, and cites the ability to pre-screen vehicles before they approach the Ground Transportation Center as an integral part of security. Some very simple calculations show this to be an extremely optimistic expectation in terms of prevention. Current, developing and anticipated surveillance technology may offer improved detection and interception, but the distances covered by vehicles at various speeds (whether at normal or excessive traffic flow rates) significantly limit the ability of responding security or law enforcement officers to prevent a determined attack. A number of examples of the speed of attack execution exist, such as terrorist bombings of military installations overseas. A vehicle traveling a linear mile at 20 mph would cover the ground, if unhindered, in 3 minutes; at 40 mph, in 1.5 minutes. Some type of substantial physical obstacle, such as a hydraulic arrest barrier built into a choke point, should therefore be part of the roadway design. Such equipment does need some visibility for deterrent value; in a multi-lane setting, the barrier could be used to moderate traffic volume for other goals. We request that LAWA comment on roadway design from a security perspective, including the concept outlined above.

Security features for access to/from the Intermodal Transportation Center and the Rental Car Facility are not discussed in Chapters 2.3.2.3 and 2.3.2.4. We thus repeat our previous comments on controlled choke points, and request that LAWA provide discussion of security design. The reduction of people and vehicle density is but one layer in the defensive design that will allow the 'protection, detection, assessment, and response' concept to become reality. The fact that a target density at one location is reduced from say, 1000 to 100 people will not in itself deter an attacker. The possibility remains that a back up of people could be orchestrated to deliberately increase congestion, density and target volume. This possibility must be addressed at every airport ground processing facility in order to eliminate weakness in the overall security plan and avoid the need to later retrofit the roadways. The suggested control would also apply to design of exit roads, to prevent reverse flow access by an attacking vehicle. The intermodal and rental car facilities would probably not benefit from as much close-in law enforcement and security personnel coverage as the Ground Transportation Center and Central Terminal Area. This compounds the need for optimum security design features on roadways and building access. Please comment on these points.

Discussion of the Air Cargo Roadway (§2.3.2.5) offers no discussion about security planning, conveying the assumption that there are no security considerations. Is this a correct assumption? Similarly, there is no discussion of security planning for Off-Airport Public Road Access (§ 2.3.3), conveying the assumption that there are no security considerations. Is this a correct assumption?

In §2.3.6 it is noted that the proposed 12,400-stall employee garage (accessed via Pershing Drive) would "*be designed to help diffuse blast impacts from surrounding vehicles. It would be designed with a security-screening checkpoint for all employees using the garage.*" Why does LAWA emphasize this point for the employee parking facility but not for public parking facilities at the Ground Transportation Center, the Intermodal Transportation Center, or the rental car facility?

Discussion of the Automated People Mover (§ 2.4 et seq.) touches briefly on security in a reference to video surveillance. We have indicated previously our concern about the vulnerability of the Automated People Mover, but would add that the expected security issues and management plans for the Automated People Mover deserve more public disclosure. Please provide an assessment of this risk and the steps proposed to address it.

In discussing Cargo Facilities, Chapter 2.5 acknowledges that new security requirements are being developed by the TSA and advises that "*LAWA would incorporate any new requirements into the cargo facilities as those standards are developed.*" This section does not adequately address LAWA's own 'industry capability' -- i.e. using its own initiative to offer options. The future direction of air cargo security management may not be fully known from a regulatory perspective, but in terms of public safety we believe that it would be responsible for LAWA to pioneer its own air cargo security standard. Alternative D by virtue of its title claims to answer security concerns and to offer innovation in the process. Yet innovation is decidedly absent from the cargo aspect of the plan. The ultimate test may come from an attack on commercial aircraft via air cargo: adequate warnings exist in industry circles to justify a stronger effort in this regard. We request that the SDEIS/EIR provide more detailed discussion of air cargo security measures, and respond to the suggestion that LAWA pioneer its own standards.

Among the measures that could be considered for air cargo facilities is a plan that would allow airline operators to provide, at short notice, an integrated roadway and security system to screen and clear inbound vehicles, and a 'cold' or 'hot' operational facility for dual technology screening of

outbound cargo. In combination, these facilities could routinely earn additional airport revenue and facilitate business continuity during periods of high alert. Please comment on this suggestion.

Addendum Illustrations: The various plan drawings and artists impressions found in the Master Plan Alternative D documentation are helpful and informative. There are, however, several considerations for improving public articulation. Residents of the surrounding environs are a valuable part of airport protection. The eyes, ears and voices of local residents can provide superior protection of community assets. This holds true even when compared with trained law enforcement personnel who have access to advanced technologies. Citizens and local residents who perceive that they have a stake in the future of their airport, and who are consulted in the security planning aspects, are most likely to participate constructively. What efforts have been or will be taken by LAWA to provide public education sufficient to harness this resource?

4.1.5 Review of Appendix I: Comparative Security Analysis

The Master Plan Draft Addendum refers to Appendix I as “*a detailed assessment of the security and safety features of Alternative D.*” This statement, combined with the lack of detail in other Master Plan documents, creates high expectations as to the quality of its articulation. In practice, our review has found the experience to be disappointing. The discussion is inconsistent with other documentation and falls short of the detail that should be available for public scrutiny. We are in a new era of risk management. Traditional or conventional thinking will not successfully address future vulnerabilities unless there is a respectful treatment of the public debate. The physical and operational reach of the defensive concept will extend beyond the footprint of the airport infrastructure. In fact, the security component will have environmental effects that are unprecedented in American commercial airport planning, particularly in urban and suburban settings. The Master Plan Alternative D must offer detailed projection, measurement and quantification of these impacts.

Discussion of the Concept: The document states, on page I-2 of the Executive Summary, “*The first level (Level 1) entails screening of all persons and bags prior to entering the Central Terminal Area. Level 1 screening is focused on preventing attacks on the ground and ensuring a safe passenger environment. This level of screening will occur prior to entering the Automated People Mover system or FlyAway shuttle buses and focuses on weapons and explosive.*” This directly contradicts the ‘random screening, sniffing dogs’ explanation in the main Draft Addendum document; clarification is requested.

On page I-4 of the Appendix, under Methodology, reference is made to the Department of Homeland Security and General Accounting Office validation of “concentric rings of security” to bring protection, detection, assessment, and response” capability ‘*to the extended airport perimeter*’. The following statements from that Chapter appears to contradict the approach offered in the prior two documents:

‘Anyone entering the airport property whether to visit or travel will undergo security inspections. There are at least two levels of personnel and baggage inspection that will take place. Level 1 inspection requires screening for explosives and weapons prior to transport by the Automated People Mover or FlyAway shuttle bus to the Central Terminal Area. Using current technology, Level 1 inspection would include screening of persons and bags similar to checks made upon entering federal buildings today. These checks should be

designed to be as unobtrusive and not impede the flow of transportation to the Central Terminal Area and should take advantage of the emerging technology. Level 2 inspections will consist of current security screening criteria as mandated by TSA for departing passengers and baggage which is more intrusive and detailed than level 1'.

We offer the following observations on the above excerpt, and request that LAWA provide comment and clarification for each point:

- ▶ Level 1 inspection as described here does not match the 'random selection, sniffing dogs' explanation offered in the Draft Addendum.
- ▶ There is no mention of profiling people and baggage for selective screening.
- ▶ The stated similarity to 'checks made upon entering federal buildings today' is meaningless to people who have never seen or experienced the federal security screening process.
- ▶ At federal buildings 100% of those who enter are screened, but these systems rarely (if ever) encounter baggage in size and volume such as will be common to an airport.
- ▶ The statement above contradicts itself: the process for federal buildings is obtrusive and would impede flow if applied literally as a Level 1 screening protocol.
- ▶ The possibility of 2 levels of screening that are both obtrusive, even with Level 1 proving to be selective, implies a need to estimate consequential density effects that might in some circumstances defeat the desire to disperse people rapidly into the airport controlled areas.
- ▶ The reader is left wondering whether there is agreement and/or coordination between the planning entities on security policy and practice.

The same page refers to Figures 4-1 & 4-2 as illustrations of the concentric rings of security and deterrence strategy respectively. These very simplistic figures are of no value in helping the public to understand what the strategies mean for LAX, and no other drawings are included in Appendix I. Why is this not done, given the proliferation of site drawings and artists' impressions in the other parts of the Alternative D documentation? We ask that LAWA superimpose the concentric rings over the airport plan and explain the resulting figure. The following statement from the same page is offered for its relevance to further comment:

"PDAR facilitates the detection of possible malevolent acts prior to the hostile force coming within range of the target. By increasing the distance between critical areas and the point of detection, law enforcement officers and security personnel have additional time to assess the act as benign, dangerous, or overtly hostile, and respond appropriately."

We offer the following observations on the above excerpt, and request that LAWA provide comment and clarification for each point:

- ▶ Is it correct to assume from the statements about bomb threat dispersal that 'critical areas' include public areas where concentrations of people can be expected (e.g. the Ground Transportation and Intermodal Transportation Centers, the Central Terminal and perhaps to a lesser extent, the Rental Car Facility)?
- ▶ A rough calculation of available response times (using existing travel distances and transit times) indicates that Alternative D roadway configurations will not significantly increase response time 'prior to the hostile force coming within range of the target.' What does LAWA anticipate in terms of this issue?

- By inference, the ‘protection, detection, assessment, and response’ system would prove of value only if the outer concentric circles encompass more distant roadways and areas including commercial and residential areas, beyond the immediate airport environs. Is LAWA contemplating an expansion of the concentric circles to include these areas?
- Implementation of a multiple concentric ring system defies imagination in its practical application to LAX. The airport has an irregular property boundary that may be poorly suited to this system. There is no logical center point for the concentric rings, apart from the large Air Operations Area, and the critical areas at LAX are disparate and scattered. In this setting, what is the feasibility of developing the concept with a series of overlapping concentric rings?

Discussion in Ch. 5 (Threat) evaluates LAX as a target. This is a complex topic; we understand that evolving trends in terrorist tactics may unexpectedly shift some of the security emphasis and strategy over time. However, we believe that the threat may have been understated and ask for further discussion and comment on this issue.

The discussion of Potential Mitigations (pp. I-12, I-13) describes security measures that will be applied to MTA Green Line connections with the proposed Intermodal Transportation Center. The discussion refers to use of Closed Circuit Television surveillance and related intelligent devices (as yet unidentified), and specifically mentions facial recognition technology. Several security industry reports in 2002 and 2003 have discredited the so-called ‘face in the crowd’ facial recognition applications. Original hopes for this technology were overly optimistic, and recent experience has shown this application to be flawed. In a number of cases (for example, Ybor City, Tampa, FL) the systems have been withdrawn from use.²² Further comment will be made later in regard to use of an array of technology and the finite value of detection data inflow.

The final paragraph discussing the MTA Green Line states that “*The Green Line connection enhancements in Alternative D provide for a better security solution because no unscreened people or luggage would be permitted to enter the Central Terminal Area.*” This suggests 100% screening of people and bags, yet there is no reference elsewhere in the Addendum or Supplement to confirm this. Please comment on whether 100% screening will be provided.

There is also no discussion of the planned accommodation for and type of screening equipment, other than a vague mention: “*The MTA Green Line connection facilitates the future employment of security technology allowing a level of initial screening to occur prior to entering the Intermodal Transportation Center or Central Terminal Area.*” What form of screening will actually take place there initially, and to what extent? What increase in screening activity is planned or accommodated in the contingencies for change?

Chapter 6.2 offers a more comprehensive description of the Intermodal Transportation Center. The Comparative Analysis acknowledges that the Intermodal Transportation Center is an integral part of the concentric rings of security and ‘protection, detection, assessment, and response’ concept. The concentric rings processes are described, with the final stage described thus: “*Prior to boarding the APM, all people and bags will be screened using appropriate technology to identify weapons and explosives.*” Two benefits are cited: one is that it would permit initial screening of passengers and

²² Note that biometric facial identification systems, which are used to match individuals on a one-on-one basis, are a different form of this technology and continue to show successful results.

vehicles that without the reconfiguration would not occur; and the other is that it adds a measure of protection to passengers using the APM as they move to the Central Terminal Area. This appears to contradict other elements of the Master Plan documentation, raising questions about the consistency between security components. LAWA should define the word 'screening' and use the classification 'Level 1' more consistently. Otherwise this suggests the emergence of different security standards for access to the Automated People Mover and Central Terminal Area.

Pages I-16 and I-17 cover general security matters pertaining to the reconfigured roadways. Again we note that security technology is a valuable adjunct to trained security patrols but it is not a panacea; it is instead a management tool. Please articulate the contingency plan for interception and management of roadway incidents with minimal disruption to airport operations. This is particularly important at the policy setting stage, as large projects are notorious for paring back security expenditures and thereby compromising protection standards. Will LAWA policy identify agreed-upon security standards so that this does not occur?

In practice, the performance of Closed Circuit TV will depend on the ratio of trained personnel to monitoring devices. Although the stated benefits of roadway monitoring are attractive, the increased data will require monitoring, interpretation and action. How much thought has LAWA given to the risk of data saturation? Over-dependence on security technology may lead to higher risk of error and, ironically, diminished protection. Occupied space is projected under this plan to increase from 3.9 to 6.8 msf. In combination with increased separation distances, this increase will impose substantial new constraints and demands on emergency and enforcement response, and also upon patrol/deterrent services.

Mitchell Gray, in a University of British Columbia paper title *Urban Surveillance and Panopticism* (<http://www.surveillance-and-society.org>) explores many of the more complex issues associated with surveillance in the community. It is worthy reading for any elected official attempting to understand the implications and potential unintended consequences of surveillance systems. The basic message to be gained from Gray's treatise is contained in the following extract: "*It is rapidly becoming an urban instinct to grasp at security through surveillance and knowledge, but this, paradoxically, may add to urban insecurity in a fundamental way: by transforming society in unforeseen directions. There is a threshold point in urban surveillance beyond which quantitative change – the addition of devices used and areas watched – becomes qualitative change.*" Please comment on how LAWA has addressed the potential for over-dependence on security technology at LAX as part of the proposed Master Plan improvements.

A review of the Ground Transportation Center in Appendix I (Ch. 6.4) restates the threat and target dispersal philosophy along with the 'protection, detection, assessment, and response' protocols. According to discussion on page I-19, passengers will go through a well-organized Level 1 screening point at the Ground Transportation Center before transport on the Automated People Mover to the Central Terminal Area. The Level 1 screening serves to insure the integrity of the Automated People Mover and common areas of the Central Terminal Area, and represents the first opportunity to check passengers and employees for concealed weapons and explosive devices. Yet again there is a clear contradiction with the main part of the Draft Addendum, reinforced by a listing of measures that makes reference to design and installation of passenger and baggage screening devices; please clarify. Additional comment and questions are provided below:

- Is it the planned intention to have two levels of screening, to include 100% of pedestrians accessing the APM and Central Terminal Area?
- How would 100% screening of Level 1 people and baggage affect the risk of congestion and increased people density at the Ground Transportation Center and other remote locations? Has LAWA analyzed this risk? If so, where are the results?
- What ergonomic design factors will optimize rapid movement of people and bags? Has LAWA considered the impact of Level 1 screening on the elderly, infirm, and people traveling with small children?
- Has any field market research been conducted to assess the tolerance for earlier arrivals to negotiate two levels of screening and transportation of baggage between those two levels?

Discussion of the Rental Car Facility (Appendix I Ch. 6.5) repeats the intention to screen all personnel from the Rental Car area to the Automated People Mover. However, the same discussion notes: *'should the current Central Terminal Area roadway need to be secured' inspection of an estimated 1 million shuttle bus trips annually would be time consuming and subject to human error even if state-of-the-art security inspection equipment was employed*'. If Alternative D removes vehicular traffic, and thereby mitigates vehicle bomb risk, then would not the passenger and baggage security factor shift to the Automated People Mover? The APM system could become an attractive and vulnerable target. We are therefore concerned about the potential need to police and manage a much larger area (including an occupied mix of separate facilities), that may from the outset require equal standards of screening at Levels 1 and 2. Please comment on this concern.

The Rental Car Facility mitigation measures offer a blend of logical and speculative measures, including the discredited facial recognition system. We again raise earlier comments about discredited systems, data saturation and over-dependence on technology. This is particularly pertinent since the assessment does not refer to an equivalent demand for the increased training and numbers of security operatives (ranging from technicians through guards to airport dedicated law enforcement personnel). Please comment on LAWA's plans with respect to the presence and role of security personnel at the Rental Car Facility.

We request that LAWA provide a security deployment projection for Alternative D, together with a security technology and equipment schedule. Please illustrate how 'protection, detection, assessment, and response' can be accomplished using only technology available today, and describe any credible security equipment advances that can be expected over the next 5 years that might justify an investment in this program. It may be unwise to count on as-yet undeveloped technologies, particularly since reliable and proven technology is with us today, sufficient for planning purposes. More problematic may be the use of human resources, including appropriate numbers, competence and strategic locations.

The comparative analysis in Chapter 6.6 indicates that the Automated People Mover will be a key component for dispersal of vehicular traffic from the Central Terminal Area roadway network. This may be true, but could LAWA accomplish the same dispersal by reducing the distance between the remote ground processing points and the Central Terminal Area? Please provide a vulnerability analysis to address this issue. Further comment and questions are provided below:

- Please provide additional discussion about screening for weapons and explosives at the inbound remote Automated People Mover station access points

- ▶ Please discuss the security logistics and practical challenges of handling heavy baggage, multiple bags, and elderly and disabled passengers and children when loading and unloading the Automated People Mover. It is extremely difficult to imagine how screening, loading and offloading of passengers and baggage could be accommodated at the Ground Transportation and Intermodal Transportation Centers and the Rental Car Facility, with sufficient frequency to achieve the level of service promised in the Plan -- especially with the reconfiguration objective of rapid dispersal of people.
- ▶ The Draft Addendum states (p.2-37) "*It is also assumed that luggage carts would be allowed on the Automated People Mover and highly utilized in the transfer of people and baggage.*" This chaotic image invites questions about safety factors and load capabilities, neither of which is discussed in the Appendix I security assessment. Please address this issue.
- ▶ Please provide an exhibit showing street-to-departure ergonomics, flow and density patterns, and screening equipment layout of the remote people mover access points. Although security screening equipment is implied, space utilization is at odds with this statement from page 2-37: "*it is anticipated that passenger assembly would be limited to the passenger platform.*"
- ▶ The prevention of unscreened vehicular and bomb access to the Central Terminal Area could be offset by the APM: the train could actually carry the device to its target if Level 1 does not screen for explosives carried on the person (as in suicide attacks in Israel). Magnetometers do not detect explosives. Please address this potential security threat.
- ▶ The APM could be attacked via vehicles using Century Blvd. and 98th Street, and/or from commercial buildings and hotels overlooking the Automated People Mover guide way system. Please address this potential security threat.
- ▶ The primary vulnerability appears to come from the track distance and elevated nature of the Automated People Mover, and its target worth (i.e., elimination of a critical airport transit link, serious disruption to operations, high casualties, public terror and a prestigious but discredited security program). In effect, the Automated People Mover may serve to reintroduce the target potential that Alternative D was purportedly designed to reduce.
